22   **Supplementary Notes**

23

24   **Note 1: Additional results and discussion of the ToF-SIMS analysis**

25   The principal results of the ToF-SIMS analysis are described in the main text. Here we

26   provide additional experimental results and discussion to support the conclusions drawn in the

27   main text.

28   *Fragment identification*. In total 71 fragment ions were identified in positive mode and

29   173 in negative mode in the ToF-SIMS runs of the fiber sheaths. Identification was based on

30   the exact mass in ToF-SIMS analysis and was checked for identity and purity with the

31   Orbitrap-SIMS runs. For transition metals and S, the isotopic mass distribution was verified.

32   For Ni, the four main isotopes (^{58}Ni, ^{60}Ni, ^{61}Ni and ^{62}Ni) were found with the expected

33   isotopic abundance, whereas the minor isotope ^{64}Ni showed mass interference from a low

34   amount of Zn. For Cu, both isotopes (^{53}Cu and ^{65}Cu) showed the expected abundance. For Fe,

35   the two main Fe isotopes (^{54}Fe and ^{56}Fe) showed the expected abundance, whereas the minor

36   Fe isotopes (^{57}Fe and ^{58}Fe) showed mass interference from an unknown source and Ni

37   respectively. Zn counts were low and not reliable as the main isotope (^{64}Zn) showed mass

38   interference from ^{64}Ni. Other transition metals found in metalloproteins like Mn, Co, Mo and

39   W were not detected or had very low counts. The main isotopes of Sulfur (^{32}S and ^{34}S) also

40   showed the expected abundances, whereas the minor isotopes ^{33}S and ^{36}S showed mass

41   interference from an unknown source. Assignment of the identified fragment ions to

42   biochemical components of intact cable bacteria and the fiber sheath was based on

43   literature[14–20] and specific depth profiles (see Supplementary Data 1 and 2, Fig. 1, and

44   Supplementary Figure 1).

45   *Transition metals.* The ToF-SIMS depth profiles of Ni and Fe are discussed in detail in

46   the main text. Cu showed a peak at the first data point of the depth profile in both the fiber

47   sheaths and the intact cable bacteria (Fig. 1D, Supplementary Figure 1A-B, Supplementary

48   Figure 11), though with a highly variable count number. This surface peak and its variability

49   between samples was consistent with our LEXRF analysis (Fig. 3), which also showed a

50   highly variable Cu signal. However, Cu counts from STEM-EDX analysis and the majority of

51   the ToF-SIMS depth profiles in the fiber sheaths were low compared Ni counts. This suggests

52   that Cu is not present in high concentrations, but likely derives from an variable impurity that

53   adsorbs to the sample surface at some stage during sample preparation (either cable bacteria

54   collection, fiber sheath extraction procedure) or analysis.

55   *Polysaccharide fragments.* As discussed in the main text, the basal polysaccharide

56   layer (Fig. 1D and 1E) most likely consists of peptidoglycan, which consists of an acidic

57   amino sugar backbone interconnected by short peptides[21]. We therefore expected to find

58   fragments that contain both oxygen and nitrogen, as derived from the amino sugar backbone

59   of peptidoglycan. To verify that we can detect peptidoglycan specific fragments among these

60   O- and N rich fragments, we performed ToF-SIMS analysis of four protein and

61   polysaccharide reference samples: Bovine Serum Albumin (BSA), starch, pectin, and

62   peptidoglycan (Supplementary Figure 8). Although the mass spectra of these reference

63   samples showed major differences in both negative and positive mode (Supplementary Figure

64   8), we could not detect any peptidoglycan specific fragments in the fiber sheaths. Moreover,

65   fragments that contained both nitrogen and oxygen showed either the same depth profile as

66   amino acid (protein) derived fragments (i.e. an initial peak at the start of the depth profile), or

67   were specific for nucleic acids that showed low counts and variable depth profiles

68   (Supplementary Data 1 and 2). The latter suggests that some residual DNA/RNA remains

69   associated with the fiber sheaths after extraction. The lack of peptidoglycan specific

70   fragments is most likely due to the abundance of protein in the fiber sheath, which leads to

71   high signals of amino acid derived fragments that mask fragments derived from

72   peptidoglycan. Further work is needed to confirm that the polysaccharide layer is indeed

73   made of peptidoglycan.

74   *P-containing fragments.* The fiber sheaths also showed high counts of various P-

75   containing fragment ions in both positive and negative mode (Supplementary Data 1 and 2)

76   with variable depth profiles between runs. The likely source of these P-containing ions is the

77   poly-phosphate granules that are commonly found in cable bacteria[22]. Likely, the poly-

78   phosphate granules are incompletely removed during the fiber sheath extraction procedure,

79   and they comprise the particles that are seen in the interior of fiber sheaths during STEM 3D-

80   tomography (Fig. 1A).

81   *S and Ni containing fragments in negative mode.* Negative mode ToF-SIMS depth

82   profiles showed a subsurface peak of various S-derived anions ($^{32}S^-$, $^{34}S^-$, SH^- and S_2^-) at

83   approximately the same position as the Ni peak in positive mode (Fig. 1D and 1E,

84   Supplementary Figure 1, Supplementary Data 2). In addition, a substantial number of Ni-

85   containing fragments were found in negative mode that also showed this distinct subsurface

86   peak (Fig. 1D, Supplementary Figure 1, Supplementary Data 2). The most prominent Ni

87   containing fragments were a series of $Ni_xS_y^-$ cluster ions (x = 1 to 6, y = x +/- 1, both ^{58}Ni and

88   ^{60}Ni isotopologues were detected, Supplementary Figure 9). Additionally, we found $NiC_xN_x^-$

89   (x = 1 or 2) and $NiCSN^-$, and even a small but detectable Ni^- signal (Supplementary Data 2).

90   All these Ni-containing fragments showed a similar sharp subsurface peak in the depth profile

91   as found for Ni in positive mode (Fig. 1E). The observed NiS clusters are most likely formed

92   in the ion plume of the ToF-SIMS rather than being natively present in the fiber sheath[23–25].

93   As a control, we analyzed an artificial mixture of protein (BSA) and freshly precipitated

94   mineral NiS, and we indeed observed the same $Ni_xS_y^-$ cluster ions (Supplementary Figure

4

95   9D). Still, due to an effect called self-focusing[23], the detection of NiS clusters suggests that Ni

96   and S must be present in close proximity in the fiber sheath (lateral (XY) within <0.5 nm,

97   depth (Z) within <2 nm), otherwise they would not be formed in the ToF-SIMS ion plume.

98   This observation is hence in agreement with the presence of a S-ligated Ni cofactor in the

99   fiber sheaths.

100   We also found a number of organic S fragments in negative mode ToF-SIMS spectra

101   (Fig. 1E, Supplementary Figure 1, Supplementary Data 2). Most of these fragments showed a

102   similar depth profile as S^- with a sharp subsurface peak on top of a general S signal, and so

103   again, we cannot exclude that they were formed during ToF-SIMS analysis. However, two

104   fragments ($C_2S_2^-$ and $C_2S_2H^-$) showed specific depth profiles, with the subsurface peak much

105   more pronounced than for S^- (Fig. 1E). This suggests that these two fragments originate

106   directly from the fiber sheath. These fragments could indicate that the fiber proteins are rich

107   in disulfide bridges (C-S-S-C) or they could be derived from the Ni/S group. Fiber sheaths

108   display an exceptional chemical resistance, as they remain their integrity and conductivity

109   after SDS and EDTA treatments, and this resistance could be aided by protein disulfide

110   bridges.

111   *Sputtering depth calibration.* Sputtering depth was calibrated by *in-situ* AFM height

112   measurements at three different times (Supplementary Figure 2): before sputtering, just after

113   the Ni or S peak appeared, and finally just after the carbohydrate peak appeared. Sputtering

114   depth was approximately linear with sputtering time, although the initial protein layer seemed

115   to sputter somewhat faster (Supplementary Figure 2). A representative example of the

116   resulting AFM height maps is shown in Supplementary Figure 10, where sputtering was

117   stopped at 57 sec (i.e. just after the Ni peak had emerged). There was considerable lateral

118   variation in sputtering depths for a given sputtering time as seen in transects across the central

119   cell area (Supplementary Figure 10D) and at the cell junctions (Supplementary Figure 10C).

5

120 As the junctions are higher than the cell areas (e.g. Supplementary Figure 10A), the shading

121 in sputtering seen at the cell junctions probably due the angled Ar-cluster sputter beam hitting

122 the side of the cell junction facing the beam at a higher angle whereas the opposite side is hit

123 much less. This lateral variation in sputtering rate together with the left-over cytoplasm

124 content and the presence of the cart-wheel structure at the junctions leads to smearing of the

125 ToF-SIMS depth profiles. This explains why only the first fiber sheath layer is clearly seen in

126 the ToF-SIMS depth profiles.

127

128 **Note 2: Additional results and discussion of the SDM analysis**

129 The key results of the Scanning Dielectric Microscopy (SDM) analysis are described in the

130 main text. Here we describe additional results that strengthen the conclusions obtained. The

131 finite element model we used is the same as presented earlier[5–7] except that here, fibers have a

132 core-shell structure with a conductive core and an insulating outer shell. The whole simulation

133 domain (which encompasses the ellipsoid fiber and the surrounding space) is cylindrical with

134 height 34 μm and radius 17 μm. Insulating boundary conditions are assumed on the lateral

135 and top borders of the simulation domain. A cross-section of the electric potential distribution

136 obtained from the model calculations is shown in the right insert in Fig. 5C. At the frequency

137 of the calculations (2 kHz) and for the parameters in Fig. 5, the electric potential is real, and

138 hence, the phase of the electric potential is constant in space. The length of the fiber in the

139 model is $L = 1$ μm. It has been shown previously that for $L > 100$ nm the force acting on the tip

140 is independent from the fiber length[6].

141 Supplementary Figure 12A shows experimentally derived capacitance gradient cross-

142 section profiles corresponding to SDM images (similar to the one shown in the left insert in

143 Fig. 5B of the main text) acquired at different tip-substrate distances (continuous lines,

ranging from z=60 nm to z=240 nm). The profile at z=66 nm is shown in Fig. 5C of the main

text. The dashed lines represent the result of the theoretical calculations with the model

described above for the same fiber parameters as those use in Fig. 5 of the main text (h=42

nm, w=87 nm, d=12 nm, ε_s= ε_c=3, σ_s=0 S/cm, σ_c=20 S/cm). The tip-substrate distances have

been determined from a capacitance gradient approach curve measured on a bare part of the

substrate (Supplementary Figure 12B, symbols) following procedures previously reported[5].

The calculated capacitance gradient profiles nicely reproduce the experimental ones with no

adjustable parameter. At all distances, the theoretical (and experimental) electric force phase

contrast is zero (not shown). Similar conclusions are reached if we analyze the capacitance

gradient approach curves measured on the substrate and on the fiber (pink and black thick

lines in Supplementary Figure 12B). A least square fitting of the model curves to the

experimental curve for ε_s= ε_c=3 and σ_s=0 S/cm, σ_c=20 S/cm gave d=12±2 nm (red continuous

line in Supplementary Figure 12B), in agreement with the value obtained from the

capacitance gradient cross-section profile analysis. The sensitivity of the capacitance gradient

profiles on the thickness of the insulating shell is shown by the dashed lines in Supplementary

Figure 12B for the approach curves and in Supplementary Figure 12C for the profiles at z=66

nm. In these figures we also compare the predictions corresponding to an homogeneous

conductive model, corresponding to d=0 nm (or to σ_s= σ_c=20 S/cm, dark grey line), and to an

homogeneous insulating model, corresponding to d=h/2 (or σ_c=0 S/m, light grey line). In all

cases we assumed a protein composition of all layers, ε_s= ε_c=3. The pure conductive model

overestimates the force acting on the tip, while the pure insulating model underestimates it.

We have considered other possible sets of electric parameters for the fiber to explore

alternative interpretations of the SDM results. Figs. S13A and S13B show, respectively, the

contrast values of the amplitude (in zF/nm) and phase of the electrical force for the tip at the

center of the fiber at a distance z=66 nm from the substrate as a function of the conductivity

169   of the core in the range from $\sigma_c = 10^{-9}$ S/m (insulator) to 10^3 S/m (conductor). The dielectric

170   constants have been fixed to $\varepsilon_s = \varepsilon_c = 3$ (proteins). The thickness of the insulating layer has been

171   varied from d=0 nm to d=20 nm. The calculations were done for the frequency of the

172   experiments (2 kHz). The amplitude as a function of the core conductivity displays two

173   plateaus for low and high conductivities, separated by a transition region, which tends to show

174   a third plateau not fully displayed. The phase shows a minimum for every transition region

175   mentioned above. Such behavior is characteristic of materials with (equivalent) permittivities

176   showing real (dielectric) and imaginary (conductive) parts. An analytical expression for the

177   equivalent homogeneous permittivity of the core-shell cylinder in a non-uniform electric field

178   cannot be derived, but the behavior observed is qualitatively similar to the one corresponding

179   to a core-shell spherical particle in a uniform electric field[26]. For a given measured

180   capacitance gradient contrast (grey band in Supplementary Figure 13A), one can obtain

181   couples of values for the shell thicknesses and core conductivity that match[5,27]. For instance,

182   we observe that the solution found above for the shell thickness (d=12 nm) is valid for $\sigma_c > 10^{-2}$

183   S/m (and, in particular, for $\sigma_c = 2 \cdot 10^3$ S/m as employed here). Other couples of values are for

184   instance d=5 nm and $\sigma_c = 5 \cdot 10^{-6}$ S/cm or d=0 nm, $\sigma_c = 7 \cdot 10^{-7}$ S/cm, among others. For these

185   values the same capacitance gradient profile (matching the experimental one) is obtained, as

186   shown in the Supplementary Figure 13C. However, the different couples of values predict

187   different electrical phase contrast profiles (see Supplementary Figure 13D). Only the couple

188   of values corresponding to the solution reported in the main text (d=12 nm and $\sigma_c > 10^{-2}$ S/m)

189   predicts a null phase contrast, as seen in the experimental results.

190   We have also considered a homogeneous dielectric model, with no conductivity, and

191   analyzed the (equivalent) homogeneous dielectric constant that the fiber should have to

192   explain the experimental results. A least square fitting of the calculated capacitance gradient

193   approach curves for different dielectric constants to the experimental curve measured on the

8

194   fiber gives $\varepsilon_s = \varepsilon_c = 11 \pm 3$ (see Supplementary Figure 14A). For this equivalent dielectric

195   constant value the constant height capacitance gradient profiles at the different tip substrate

196   distances adequately reproduce the experimental ones (Supplementary Figure 14B). The

197   phase contrast for this model is zero (not shown). However, a problem is that the equivalent

198   dielectric constant value found ($\varepsilon_s = \varepsilon_c = 11 \pm 3$) is much larger than values obtained, with the

199   same technique, on other (dry) bio-samples made of lipids ($\varepsilon=2$)[28], proteins ($\varepsilon=3-5$)[27,28,6,7] and

200   even nucleic acids ($\varepsilon \sim 8.5$)[5,27] (see Supplementary Figure 14C). Our composition data all

201   suggest that the fibers are made primarily of protein. During ToF-SIMS analysis of fiber

202   sheaths, some fragments derived from residual RNA or DNA were detected, but these were

203   not associated with the initial fiber protein layer (see Additional results and discussion of the

204   ToF-SIMS analysis) and it therefore seems unlikely that an isolated fiber as analyzed here by

205   SDM would contain major amounts of DNA. For this reason, the pure dielectric model is

206   discarded in favor of the conductive core-shell model.

207   We have also analyzed the homogeneity of the fiber electrical properties along its

208   longitudinal direction in view of the slight variations of the electric contrast observed in the

209   SDM images along the fiber (see left insert in Fig. 5C of the main text). To this end we

210   considered the core-shell geometrical model that accounts for the observed (tiny) height

211   variations of the fiber height (± 5 nm)[29] shown in Supplementary Figure 15A. Examples of

212   calculated longitudinal and transversal electric potential distributions are shown in figs. S15B

213   and S15C, respectively. The tip and electrical parameters of the fiber are the same as those

214   used in the calculations of in Fig. 5 of the main text, except for the shell thickness, which here

215   is d=10$\pm$2 nm. The slightly smaller value obtained, as compared to d=12$\pm$2 nm for the

216   cylindrical model, is due to the tip convolution effects included in this geometrical model (see

217   Supplementary Figure 15D), as discussed elsewhere[29]. Supplementary Figure 15E shows a

218   calculated constant height SDM image at z=66 nm corresponding to the region enclosed by

219 the dashed rectangle in the insert (which corresponds to the image in the left insert in Fig. 5C

220 of the main text). The calculated SDM image is nearly identical to the experimental one, a

221 fact that is further evidenced by comparing the capacitance gradient cross-section profiles

222 calculated on the hills and valleys of the image with the experimental ones (figs. S15F and

223 S15G, respectively). This result shows that, to a good approximation, the electrical properties

224 of the fiber are homogeneous along its length.

225   Finally, we have also analyzed the electric properties of the fibers when they are still

226 embedded within the fiber sheath by SDM. Supplementary Figure 16A shows an AFM

227 topographic image of a fiber sheath. Figs. S16B and S16C show, respectively, topographic

228 and constant height SDM images acquired in the area enclosed by the dashed rectangle in

229 Supplementary Figure 16A. The corresponding height and capacitance gradient profiles along

230 the dashed lines in figs. S16B and S16C are shown in figs. S16D and S16E, respectively

231 (black lines). The geometry of the tip has been calibrated with a capacitance gradient

232 approach curve acquired on the substrate (not shown) giving R=26±2 nm, θ=22±3º,

233 C'$_{offset}$=109±3 zF/nm. The sample geometry has been reconstructed by using a topographic

234 reconstruction procedure[29], as above (see Supplementary Figure 16D). For simplicity, we

235 have considered an equivalent homogeneous dielectric model characterized by an (equivalent)

236 dielectric constant ε_{sheath}. An example of a calculated electric potential distribution is shown in

237 Supplementary Figure 16F for a tip-substrate distance z=155 nm and ε_{sheath}=7. Supplementary

238 Figure 16E shows calculated constant height capacitance gradient profiles along the dashed

239 line in Supplementary Figure 16C for different values of ε_{sheath} (thin lines). The experimental

240 values on the hills (corresponding most likely to fiber positions) agree with the calculated

241 ones for ε_{sheath}~7−11 (except the first hill that gives a somewhat larger value). These values

242 are in reasonable agreement with those found for the isolated fiber when the equivalent

243 dielectric model is considered ε~11±3. This result implies that the electrical properties

244   obtained for the fibers when within the fiber sheath are consistent with those obtained on

245   isolated fibers. Similar results are expected for a fiber sheath model that included its internal

246   structure, composition and electrical properties (e.g. conductive core-shell model for the

247   fibers), as the one sketched in Fig. 5A of the main text. However, obtaining quantitative

248   predictions from SDM measurements for such complex model involving buried structures lies

249   outside the current capabilities of SDM[30] since too many unknowns are present in the model

250   (e.g. fiber position within the fiber sheath, number of fibers present within the polysaccharide

251   layer, thickness of the polysaccharide layer, etc.).

252

253   **Note 3: Calculations for estimating the contribution of the fibers to the fibers sheath, the**

254   **distance between Ni atoms in the conductive fibers and electron tunneling times.**

255   Electron hopping rates between redox sites in metalloproteins decreases logarithmic

256   with the distance between the redox sites[31]. Given the relatively low Ni content of the fiber

257   sheaths of 0.017 and 0.034 Atm% as determined by STEM-EDX for two sample batches

258   (Supplementary Table 1), we tried to estimate what the inter atomic distance of the Ni atoms

259   would be. At the cell area thick fiber sheaths are ca. 4 μm wide and 117 nm high (this study)

260   and contain on average 60 parallel fibers[2] that each contain a conductive core of 26 nm

261   diameter (this study). From this we calculate that the conductive fiber cores explain only 7%

262   of the cross-section area of the fiber sheath. If we do the same calculations for the total 50 nm

263   fiber with that includes the non-conductive outer shell, we arrive at a 25% contribution from

264   the fibers to the fiber sheath. Assuming that the conductive fiber core is made of protein with

265   a density of 1.4 g·cm^{-3} (density from[32]) and that Ni is concentrated in the conductive core (this

266   study), we estimate that the Ni concentration in the conductive fiber core is between 0.24 and

267   0.54 Atm% or 260 and 580 μMol·cm^{-3}, which are substantial concentrations. Further

268   assuming that Ni is homogenously distributed in the core of the fibers, this Ni concentration

269   in the fiber core leads to an interatomic Ni distance of 1.4 – 1.9 nm, which is within the range

270   as found for metalloproteins involved in electron transfer[31].

271   We then used these estimates of interatomic Ni distances to calculate electron

272   tunneling times needed to support the high average normalized currents in fiber sheaths of 28

273   nA (calculated from the standard SDS+EDTA extraction data in Fig. 4D). Estimated

274   tunneling times are 50 – 90 nsec, which is possible but on average however approximately a

275   factor 10 faster than expected for metalloproteins with similar hopping distances[31]. It seems

276   therefore unlikely that long distance electron redox hopping through the Ni/S-group can on its

277   own support the high conductivity of the fibers in cable bacteria (see Discussion in the main

278   text).

279

280

282

283
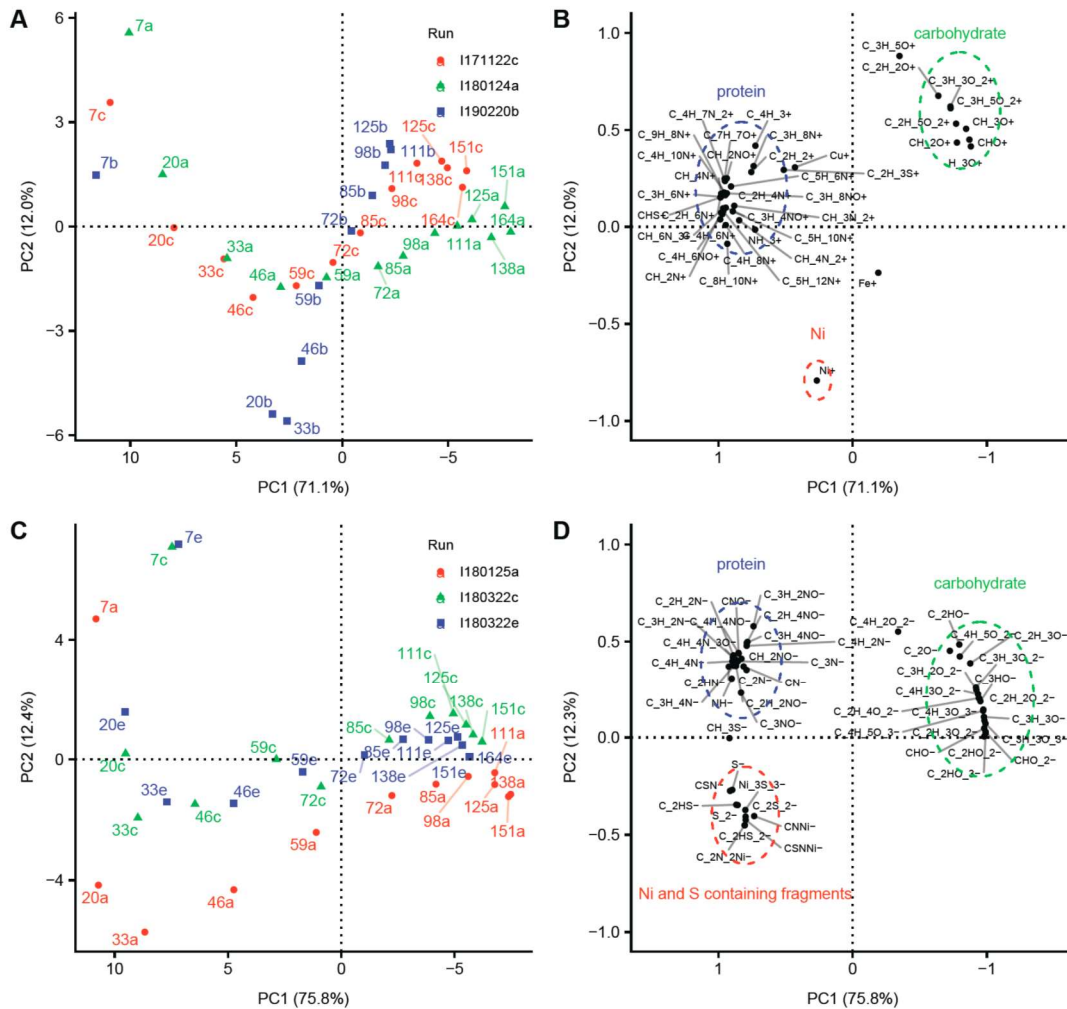

Supplementary Figure 1. Principal Component Analysis (PCA) of ToF-SIMS depth profiles for a selection of ion fragments recorded from fiber sheaths of cable bacteria. ToF-SIMS data were collected in both positive (A, B) and negative modes (C, D), and the results of three replicate depth profiling runs are shown. Counts for fragments were normalized and centered. Panels (A, C) show the scores plot (labels indicate sputtering time in seconds; colors denote separate runs). Panels (B, D) show the loading plots of the fragments. Only the data until the peak carbohydrate-derived fragments at 125-164 seconds of sputtering time were retained (representing the first half of the double-folded fiber sheath).

292
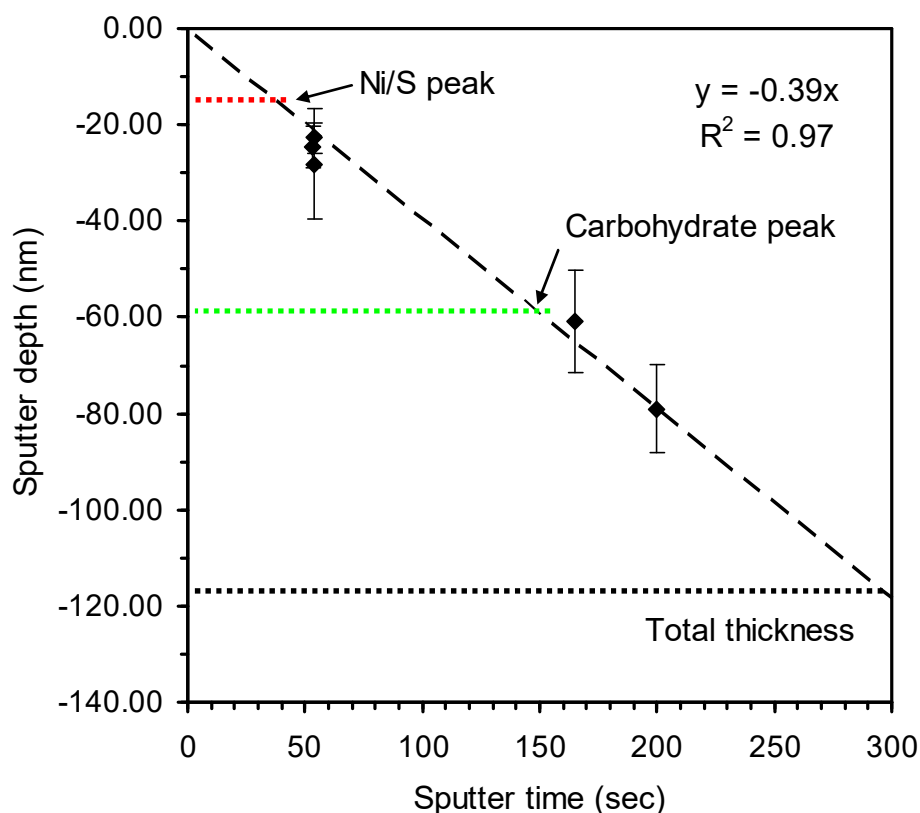

Supplementary Figure 2. Calibration of sputtering depth as a function of sputter time during

ToF-SIMS analysis. The in-situ AFM within the ToF-SIMS instrument was used to record

height images at three different times (start (sputter time = 0 sec), just after the Ni or S peak

(ca. 50 sec) and just after the carbohydrate peak (ca. 160 and 190 sec)). Sputtering depth

(black diamonds, average +/- SD) showed a linear relation with sputtering time (dashed line =

regression line through origin), though the initial protein layer seemed to sputter somewhat

faster. The total thickness of the double-folded fiber sheath amounts to 117 ± 10 nm

(determined within the middle of cells at t = 0 sec; black dotted line) and is well in agreement

with previous independent AFM imaging [2]. The average position of the Ni/S peak (15 ± 3 nm)

and the carbohydrate peak (59 ± 6 nm) are indicated (red and green dotted lines respectively,

N = 6 from 3 positive and 3 negative depth profiles in Supplementary Figure 1).

304

305
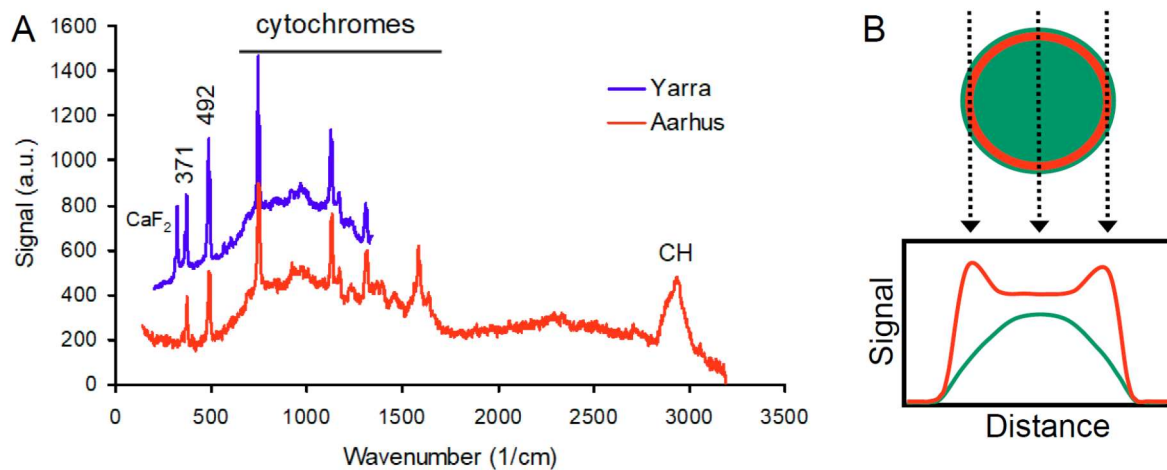

Supplementary Figure 3. (A) Green-laser Raman spectra of intact cable bacteria from

additional sediments also show the characteristic low-frequency bands at 371 and 492 cm^{-1}.

Spectra are from ca. 1 μm wide freshwater cable bacteria (Aarhus pond sediment, intact living

filaments in glass micro-chambers, average background-corrected spectrum) and ca. 1 μm

wide brackish cable bacteria (Yarra River sediment, intact filaments air-dried on a CaF$_2$

cover, average raw spectrum). (B) Interpretation of the Raman signal distribution in the scan

across an individual cable bacterium in Fig. 2B. General components of a bacterial cell such

as proteins and CH are more-or-less evenly distributed in the cross section (green filled

circle), whereas the Ni/S group is only found in the periplasmic space (red open circle). In the

depth integrated Raman signals, this leads to a unimodal distribution for Raman bands from

the general components and a bimodal distribution for the two low frequency Ni/S bands with

a peak at both edges of the filament.

318

319

320
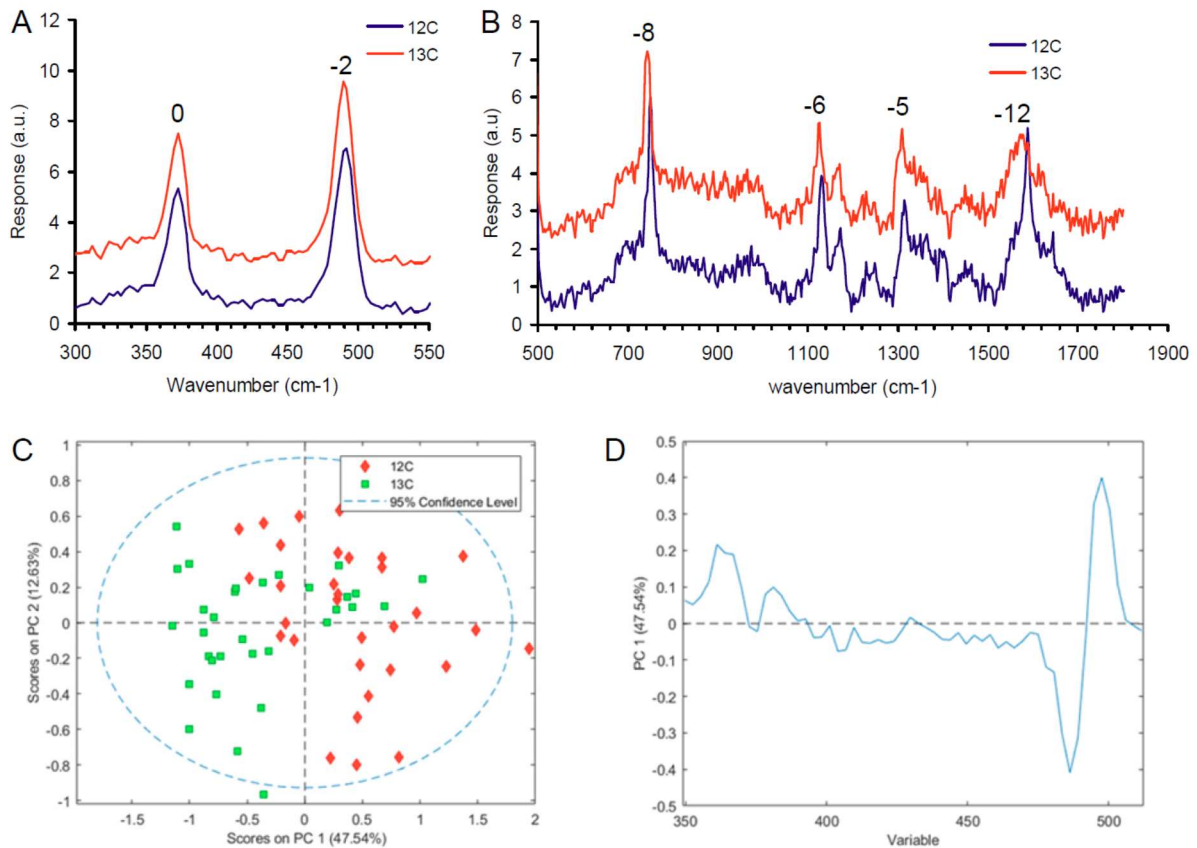

Supplementary Figure 4. Effect of ^{13}C labelling on the green-laser Raman spectra from intact cable bacteria. A) The low-frequency bands either do not shift (371 cm^{-1} band) or are only slightly affected (491 cm^{-1} band shifts to 489 cm^{-1}) by the labelling. B) The characteristic cytochrome bands clearly shift to lower values suggesting that cable bacteria filaments were highly labelled with ^{13}C. The average of N = 32 spectra is shown for both unlabeled control and ^{13}C treatments and shifts in wavenumbers are indicated. C) PCA analysis of the 350 to 550 cm^{-1} region of the spectra containing the low-frequency bands shows a difference between the labelled versus unlabeled treatments. D) Variable (wavenumber) loadings on the first PCA axis show that only the second lower band at 492 cm^{-1} shifted slightly to lower values in the labelled spectra.

331

332

333

334
Supplementary Figure 5. NanoSIMS images of A) negative ions and B) positive ions of metals from single fiber sheaths deposited on a gold-coated polycarbonate filter. In A) only the first 100 planes of analysis were selected as this most clearly showed the fibers structure in the ^{32}S image. In B) the first 50 planes were selected as this showed the fibers most clearly in the ^{58}Ni image. Independent replica's (N = 2) yielded similar results.

340

341
Supplementary Figure 6. Atomic Force Microscopy (AFM) images of fiber sheaths as

extracted with the standard protocol (A and B, SDS+1 mM EDTA for 10 min) and the high

EDTA treatment to remove Ni (C and D, SDS+50 mM EDTA for 10 min). Shown are the

height (A,C) and peak force error (B,D) data. The parallel fiber structures are retained after

high-concentration EDTA extraction. Independent replica's (N = 2) yielded similar results.

347

348
Supplementary Figure 7. AFM-IR height (in nm) and deflection maps of extracted fiber
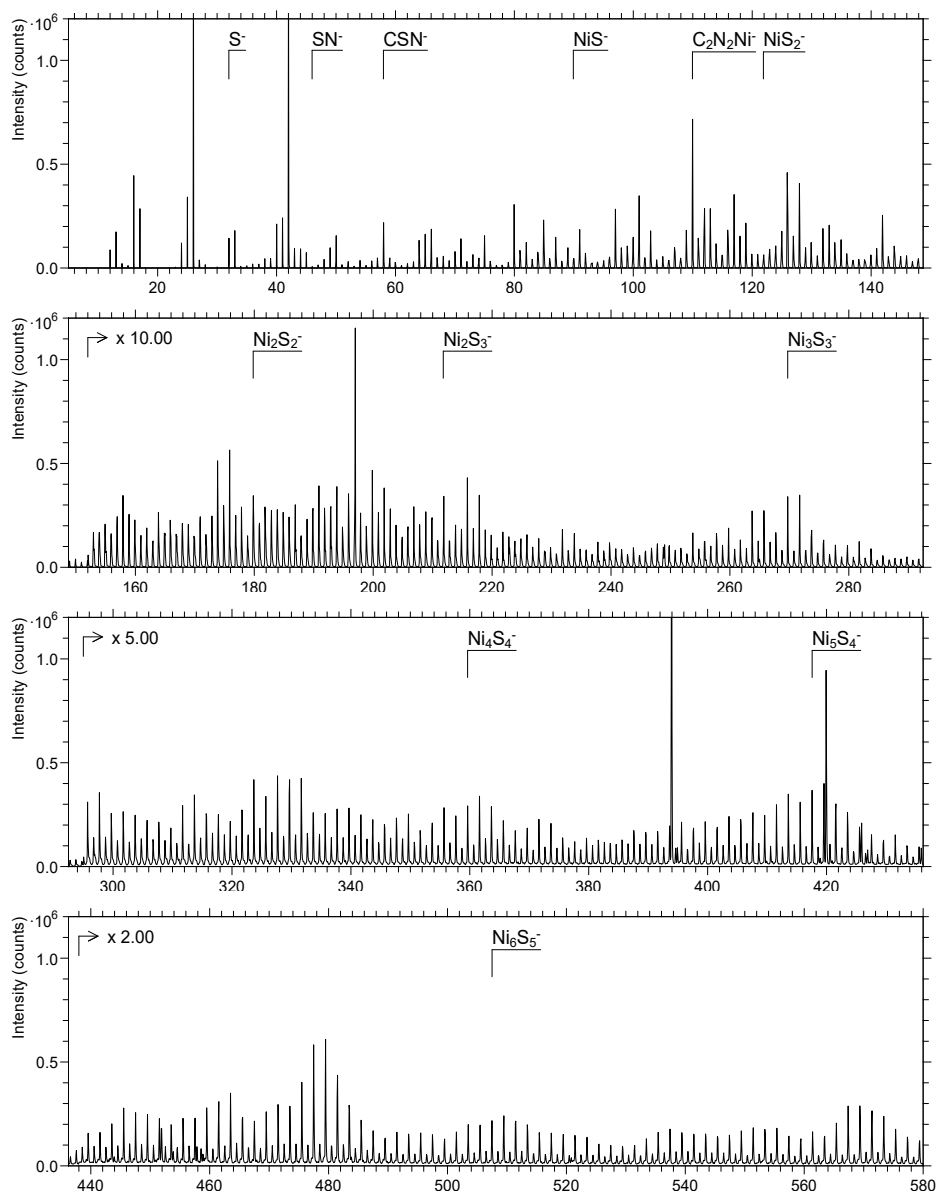

sheath showing the parallel fibers.
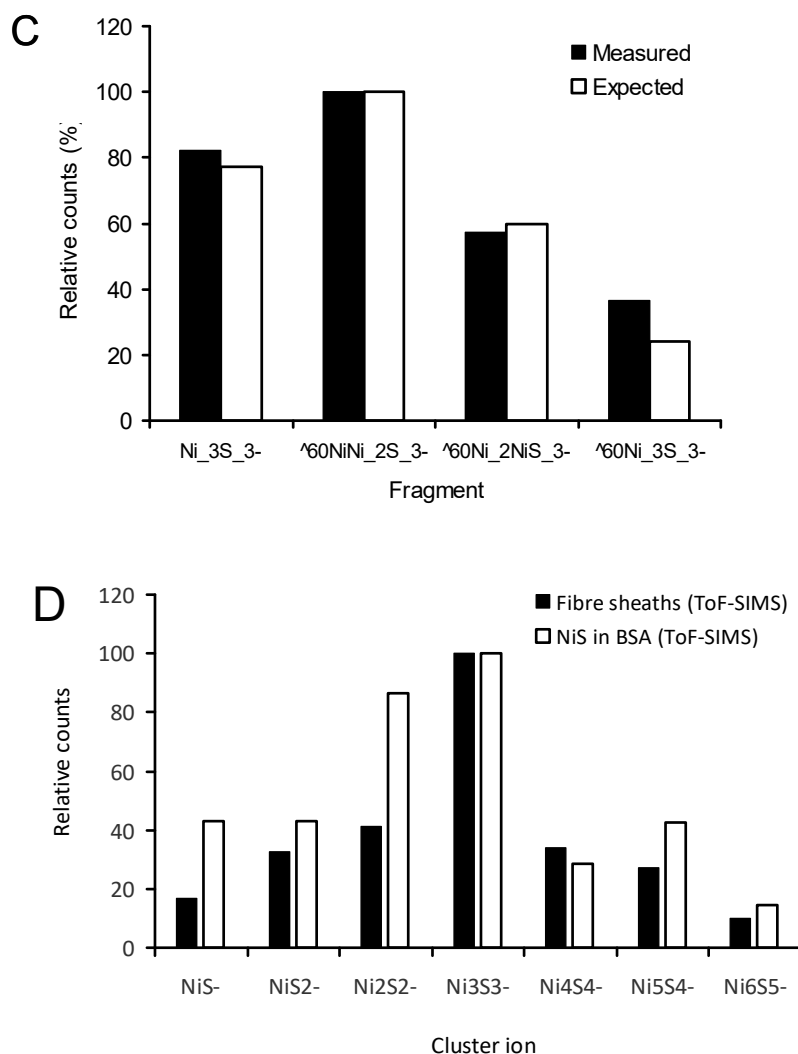

351

A

B
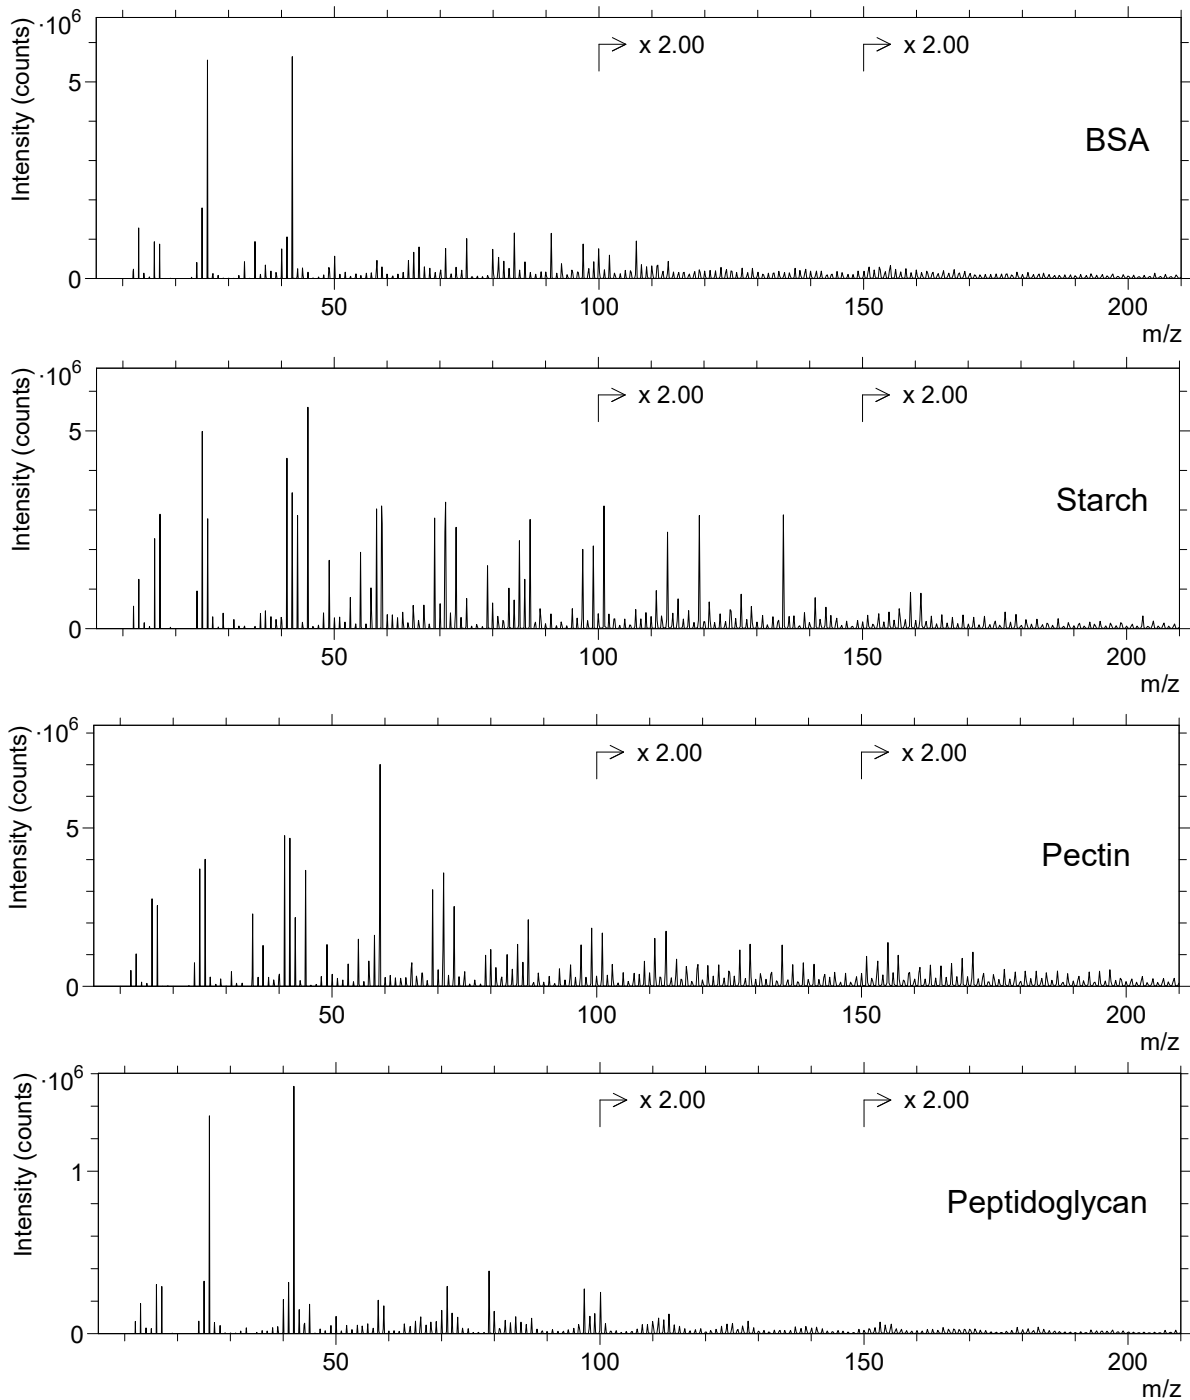

Supplementary Figure 8. ToF-SIMS positive (A) and negative (B) mode mass spectrum of additional protein and polysaccharide reference samples analyzed to aid in the interpretation of the fiber sheath mass spectra.

357

22

Supplementary Figure 9. ToF-SIMS negative mode Ni and S cluster ions from fiber sheaths and a NiS/BSA mixture. A) ToF-SIMS negative mode mass spectrum of a mixture of NiS mineral in BSA. Positions of a selection of important Ni and S cluster ions are indicated. B) Distribution of $Ni_3S_3^-$ isotopomers as a seen in the spectrum of fiber sheaths and C) compared to the expected distribution showing the good fit (similar fits were found for the other Ni_xS_y-clusters described, data not shown). D) Distribution of Ni_xS_y-cluster ions in fiber sheaths and NiS/BSA mixture (counts were normalized to $Ni_3S_3^-$). Cluster ions with 3 or less Ni atoms were sufficiently mass separated from fragments containing 2 oxygens instead of sulfur such as $Ni_3S_2O_2^-$.

368
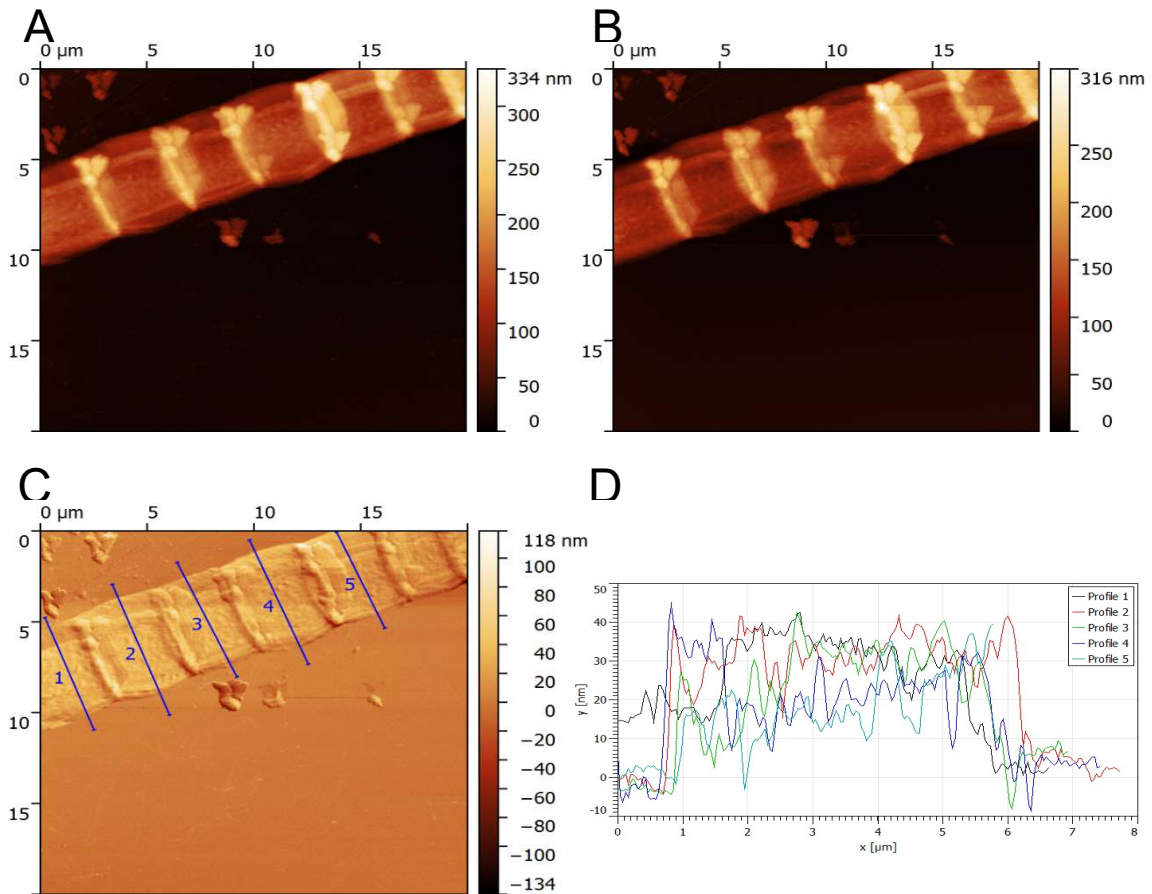

Supplementary Figure 10. Example of *in-situ* AFM calibration of ToF-SIMS sputtering

depth for fiber sheaths. AFM height map. A) mapping before ToF-SIMS analysis was started.

B) mapping after 57 sec of sputtering time (i.e. shortly after the peak in Ni^+ counts). C) The

differential image between (A) and (B) shows the amount of material removed after 57 sec

sputtering. Notice shading of the junctions with higher than average sputtering rates on the

side and lower than average sputtering rates on the opposite side. D) Height profiles as

indicated by the blue lines in panel (C) showing the lateral variation in sputtering depth.

Actual sputtering depths were calculated from height profiles as the average difference in

height of the fiber sheath (relative to the wafer surface) before and after sputtering (in this

example 22.8 ± 3.2 nm).

379

380
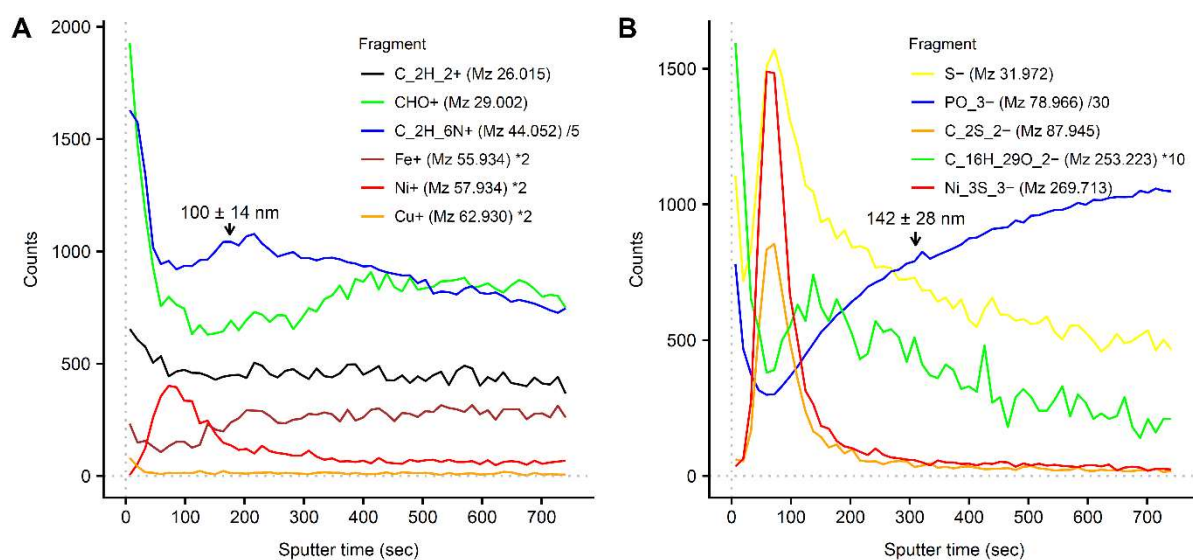

Supplementary Figure 11. ToF-SIMS depth profiles of intact cable bacteria demonstrate that

the Ni/S group is located in the periplasmic space. Representative ToF-SIMS depth profiles

from intact cable bacteria are shown in A) positive mode and B) negative mode. A selection

of fragments is shown representing the major biomolecule classes, and counts of individual

fragments were scaled to fit all data in a plot. Duplicate runs in both positive and negative

modes showed similar profiles. The counts from $Ni_3S_3^-$ are the sum of all ^{58}Ni and ^{60}Ni

isotopologues. The fatty acid fragment ($C_{16}H_{29}O_2^-$) clearly shows two peaks with the first

peak at the surface coming most likely from the outer membrane and the broader secondary

peak from the cell membrane. Phosphate (PO_3^-) also shows a first peak at the surface probably

coming from phospholipids and the secondary rise from phospholipids in the cell membrane
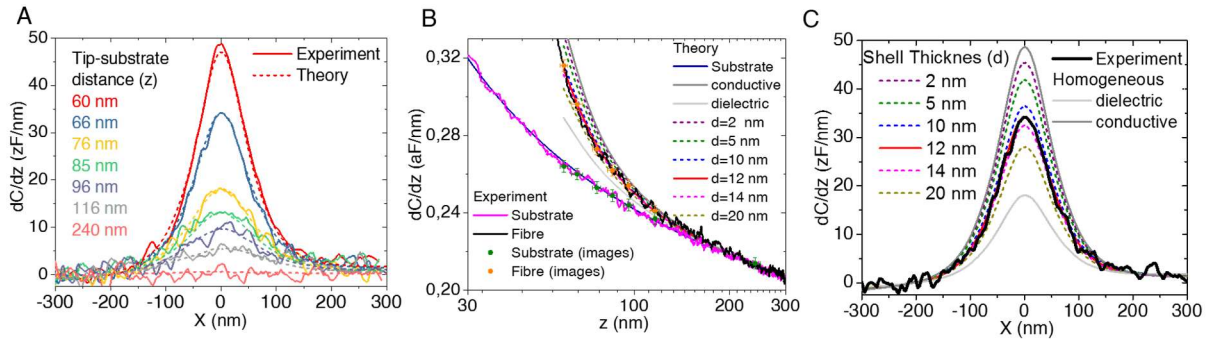

and poly-phosphate and nucleic acids in the cytoplasm. Arrows indicate sputtering depths as

determined with the in-situ AFM in the ToF-SIMS. Average sputtering rate was 0.52 ± 0.05

nm/sec, which places the Ni and S containing peak at approximately 30-40 nm depth in

agreement with the expected position of the fibers in intact cable bacteria[2].

395

396

Supplementary Figure 12. Additional information on the SDM quantitative analysis shown

in Fig. 5 of the main text. A) Capacitance gradient cross-section profiles measured

(continuous lines) and calculated (dashed lines) at different tip-substrate distances. The

profiles for z=66 nm are those displayed in Fig. 5 of the main text. The parameters used in the

calculations are the same as those of Fig. 5 of the main text: H=12.5 μm, W= 3 μm, L=3 μm,

l=1 μm, θ=22, R=54 nm, z=60 nm, h=42 nm, w=87 nm, d=12 nm, l=1 μm, $\varepsilon_s= \varepsilon_c$=3, σ_s=0

S/m and σ_c=2·10^3 S/m. B) Capacitance gradient approach curves measured on a bare part of

the substrate (pink continuous line) and on the fiber (black continuous line). The continuous

dark blue and red lines correspond to the curves that best fit the experimental results from

where the tip geometry (R=54±1 nm, θ=22º±0.5º, C'_{off}=112.5±1.5 zF/nm) and shell thickness

(d=12±2 nm) have been extracted. The dashed lines represent calculated capacitance gradient

approach curves on the fiber for other values of the shell thickness. The continuous dark and

grey lines correspond to the homogeneous conductive and dielectric models, respectively. The

green and orange symbols correspond to the values measured on the bare substrate and fiber,

respectively, on the SDM images at different heights. These values have been used to set the

tip-substrate distances of the SDM images. C) Effect of the shell thickness on the calculated

capacitance gradient profiles for z=66 nm. The meaning of the lines is the same as in B).

414

415
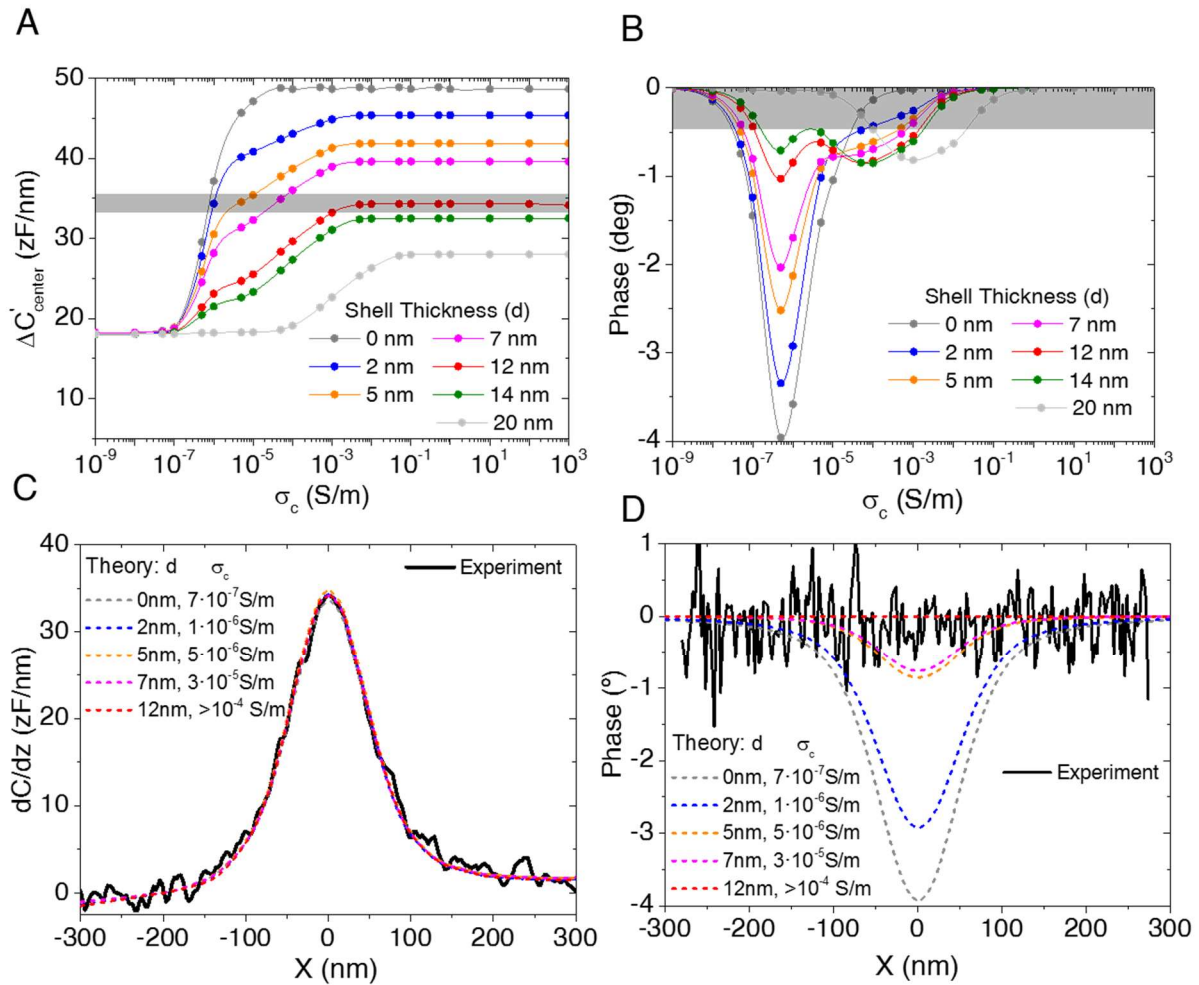

Supplementary Figure 13. Additional analysis of the core-shell conductive model used to

interpret the SDM measurements shown in Fig. 5 of the main text. A) Amplitude (in

capacitance gradient) and B) phase of the electric force contrast calculated for the cylindrical

fiber model as a function of the conductivity of the core for different values of the shell

thickness. The grey band corresponds to the experimental values extracted from the profiles

shown in Fig. 5 of the main text. Calculated capacitance gradient C) and phase D) profiles for

the couples of shell thickness-core conductivity that match the experimental measured

capacitance gradient contrast in A). The thick lines represent the experimental results (same

as in Fig. 5 of the main text). The parameters used in the calculations are the same as those of

Fig. 5 of the main text and of Supplementary Figure 12, when not otherwise stated.

426
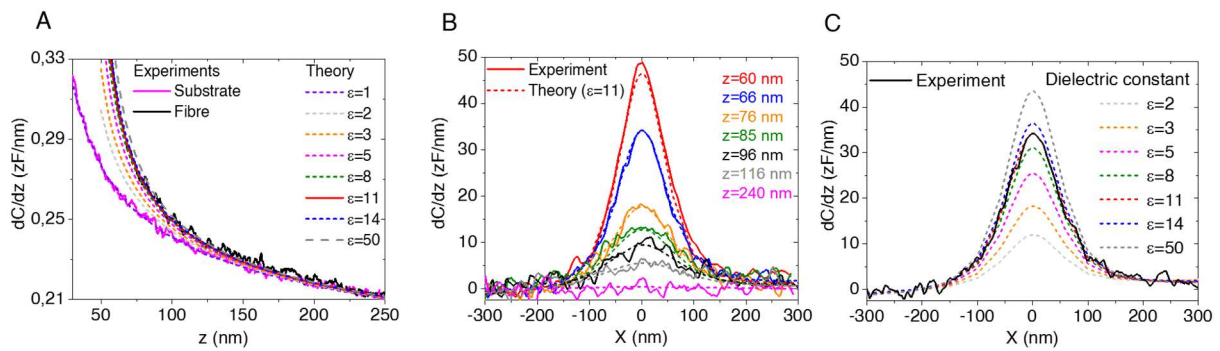

Supplementary Figure 14. Analysis of the SDM measurements shown in Fig. 5 of the main text with a homogeneous cylinder dielectric model ($\varepsilon_s = \varepsilon_c = \varepsilon_{eff}$, $\sigma_s = \sigma_c = 0$ S/m). A) Calculated capacitance gradient approach curves on the fiber for different values of the equivalent dielectric constant ε_{eff} compared to the experimental measured curves on the substrate and fiber (same as in Supplementary Fig 6B, thick lines). The best fit is obtained for $\varepsilon_{eff}=11\pm3$. B) Calculated capacitance gradient profiles for $\varepsilon_{eff}=11$ for different tip-substrate distances, and comparison with the measured profiles (thick lines, same as in Supplementary Figure 6A). C) Calculated capacitance gradient profiles for z=66 nm and different equivalent dielectric constants ε_{eff}, and comparison with the measured profile (thick line, same as in Fig. 5 of the main text). The parameters used in the calculations are the same as those of Fig. 5 of the main text and of Supplementary Figure 6, when not otherwise stated.
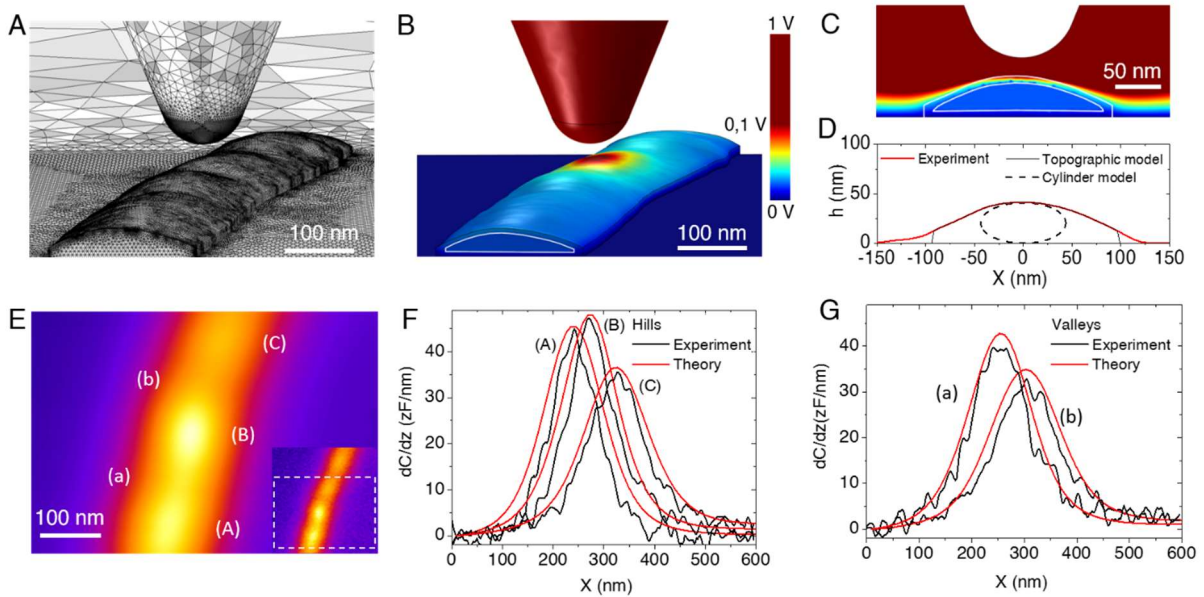

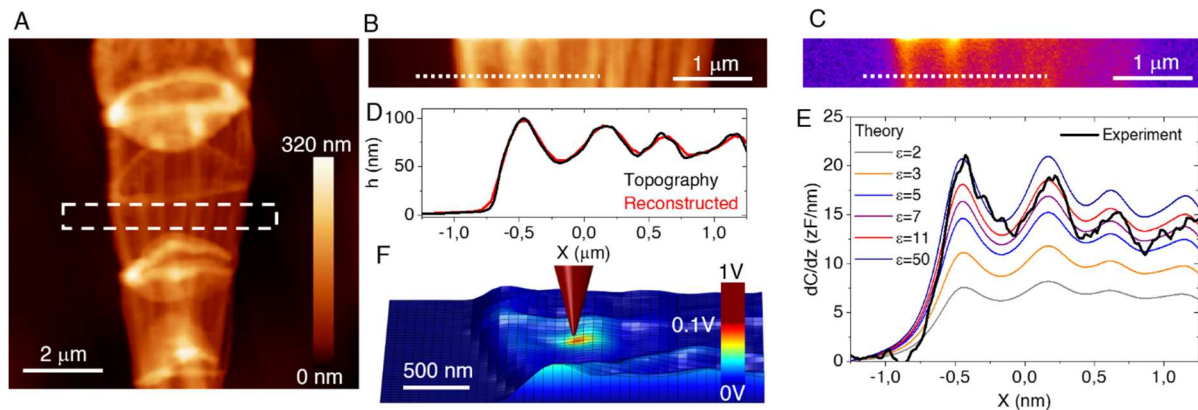

Supplementary Figure 15. Analysis of the SDM measurements shown in Fig. 5 of the main text with a geometrical core-shell model reconstructed from the measured topography. A) Detail of the geometry and mesh of the model generated from the measured topography of the fiber (corresponding to the insert in Fig. 5B of the main text). The core-shell structure is defined by assigning a sigmoidal behavior to the dielectric constant and conductivity with plateau representing the shell and core values, respectively. The thickness of the shell corresponds to the center of the sigmoid. B) Example of a calculated electric potential distribution along the fiber for z=66 nm, $\varepsilon_s = \varepsilon_c = 3$, $\sigma_s = 0$ S/m, $\sigma_c = 2 \cdot 10^3$ S/m and d=10 nm. The tip parameters are the same as those in Fig. 5 of the main text. C) Example of a cross-section electric potential distribution corresponding to B). D) Comparison of the cross-section of the measured topography (red line), the topographically reconstructed fiber model (black continuous line) and of the cylinder model (black dashed line). E) Calculated constant height capacitance gradient SDM image by using the model in A) for the parameters in B). The calculated image corresponds to the area enclosed by the dashed line in the insert. F) and G) Comparison of the calculated capacitance gradient profiles (red lines) with the experimental ones (black lines) on the hills (A,B,C) and valleys (a,b) indicated in E), respectively.

Supplementary Figure 16. SDM measurements and analysis on a fiber sheath. A) AFM topographic image of the fiber sheath analyzed. B) and C) AFM topographic and SDM constant height (z=155 nm) images measured on the region enclosed by the dashed rectangle in A). D) and E) Cross-section topographic and capacitance gradient profiles along the dashed lines in B) and C) (thick black lines), respectively. The hills in the image correspond to different fibers. F) Geometrical model reconstructed from the measured topography used in the calculations, with an example of an electric potential distribution overlaid on it. The electrical properties of the fiber sheath have been characterized by an equivalent homogeneous dielectric constant, ε_{sheath}. The tip geometry has been calibrated from a capacitance gradient approach curve on the bare substrate giving R=26±2 nm, θ=22±3°, C'_{offset}=109±3 zF/nm. The theoretically predicted capacitance gradient profiles for this model for different values of ε_{sheath} are shown in E) (thin lines). Most of the hills (fibers) correspond to ε_{sheath}=7−11 in good agreement with the equivalent dielectric constant value found on isolated fibers (ε_{eff}=7−11). For the first hill a higher value is obtained, probably indicating that two fibers are overlaid.

471 **Supplementary Table 1.** STEM-EDX element compositions for intact cable bacteria and

472 fiber sheaths. Data from two separate imaging sessions are shown (dates in first row).
