Effect of studies with high R_0 values on the performance of simple linear regression and Random Forest prediction

In this section we explain in detail how the MSE variation of simple linear regression on different indicators can be directly traced to particular combinations of missing indicator values and the value of R_0 as calculated using seroprevalence data. Consequently, we argue that this variation in the MSE should not be interpreted as increased predictive power of some indicators over others.

More specifically, we show that those indicators that have a missing value for either or both of the high seroprevalence-estimated R_0 value studies ('Czech Republic, <1967' and 'Chile (rural), 1967-68' with R_0 value equal to 19.97 and 16.53 respectively) are associated with worse MSE performance. In simple terms, the trained model prediction output cannot reach those high R_0 values in either of the two regression methods that we consider (simple linear regression and random forest). Hence the indicators which have a missing value for both those studies have an advantage in terms of the prediction MSE.

Contrary to that, that indicators which have a valid value for both those studies are associated with a higher MSE. Furthermore, this increase in the MSE is further exacerbated for those indicators which have very few valid values overall, as the higher error due to the two high R_0 studies is averaged over a smaller number of total studies. Hence, indicators with a valid value for the 'Czech Republic, <1967' and 'Chile (rural), 1967-68' studies but with valid values for a few studies overall are associated with the highest MSE.

Starting from the simple linear regression case, as can be seen in Table A (which also has a version sorted by MSE value for presentation clarity), the best performing

indicator ('Poverty gap at national poverty lines (%)' –listed in line 20 of Table A with MSE value equal to 2.73) is the only indicator having a missing value for both those studies (this indicator also has a missing value for the third highest R_0 study which is 'East Germany, 1990' with R_0 equal to 10.19).

Furthermore, 4 out of the 6 indicators that have a missing value in exactly one of those two studies, are directly following in terms of MSE performance ('Adjusted net enrollment rate, primary (% of primary school age children)', 'Prevalence of undernourishment (% of population)', 'Exclusive breastfeeding (% of children under 6 months)' and 'Population living in slums (% of urban population)' listed in line numbers 30, 41, 47 and 52 of Table A with MSE values equal to 5.35, 5.5, 5.36 and 5.39 respectively). Those 4 indicators have valid values for at least 75 studies in total. The remaining two indicators which have a missing value in exactly one of the two high R_0 studies ('Average number of people per room in occupied housing unit' and 'Total population in a household, both sexes') have valid values for only 12 and 26 studies in total (see Table A). As was described above, this practically means that the higher error due to high R_0 study is averaged over a much smaller number of total studies and, consequently, the MSE for those two indicators is much higher (33.32 and 17.4 respectively).

Considering the indicators which have a valid value for both of the high R_0 studies ('Czech Republic, <1967' and 'Chile (rural), 1967-68') the aforementioned effects result in a clear three-way division in terms of performance: A total of 45 indicators have valid values for 75 up to 98 studies and the MSE associated with them is clustered between the levels of 7.41 and 9.57 (those are the indicators listed in Table A in positions 1-19, 21-29, 31-40, 42-46, 48 and 50). A second group contains 13 indicators which have valid values for 53 up to 61 studies and the MSE associated with them is clustered between the levels of 10.15 and 12.26 (those are the indicators listed in Table A in positions 53-65). A third group contains one indicator ('Number of doctors'

consultations') which has valid values for only 25 studies in total and for which the MSE raises to a value of 26.93

A similar effect can be seen in the random forest performance results regarding the indicator subsets that are used to train and the random forest (a tabular summary is included in Table B). In the cross validation experiment conducted using only the 25 indicators that have no missing values, both the high R0 studies are present and the overall error has the value of 9.87. In the experiments conducted using the indicators that have up to 10, 20 and 40 missing values only one of the two high R0 studies is present and the overall error is lower. However, as the number of studies involved in the experiment reduces from 69 to 52 and then 32 as we allow indicators with progressively more missing values, the overall error progressively increases (8.19, 9.6 and 13.8 respectively). Finally, none of the two high R0 studies is included in the experiment conducted with the 20 indicators having up to 70 missing values and the overall error in the case attains the lowest value of 6.88.

None of those effects can be seen in the imputed results (Fig 4 of the main text), with the exception of a small increase in the max range of the error value for the indicators 'Number of doctors' consultations' and 'Average number of people per room in occupied housing unit' indicators which are the ones with the fewest valid values overall (and hence the most imputed values).

Finally, in Figs A, B we plot the MSE values calculated in the same way as for Figs 3, 4 of the main text but when the cross-validation experiment is run after excluding the 'Czech Republic, <1967' and 'Chile (rural), 1967-68' studies. In this case the highest value of R_0 as estimated from seroprevalence data is for the 'East Germany, 1990' study (R_0 =10.19). Most of the MSE variation can be seen in Fig A to be lost in this case. The only variation is a small decrease in the MSE value for the 5 indicators which have a missing value for the East Germany study ('Poverty gap at national poverty

lines (%)', 'Poverty headcount ratio at national poverty lines (% of population)', 'Prevalence of undernourishment (% of population)', 'Exclusive breastfeeding (% of children under 6 months)' and 'Population living in slums (% of urban population)') and an increase in the MSE for the indicators with the fewest overall valid values ('Average number of people per room in occupied housing unit' and 'Number of doctors' consultations'). Both those effects follow exactly the same pattern described above.

Table A: Presence or absence of the two studies with highest value of R_0 from non-imputed linear regression 4-fold cross validation experiments.

					Number
				Average	of studies
