### **Materials and methods**

#### **Samples**

We included samples of 620 Kuwaiti individuals from the State of Kuwait who were part of a larger cohort collected for studies of metabolic disorders [1–3]. The participants were recruited through the following means: (i) from visitors to clinics and Open Day Events at our institute (ii) from visitors to our campaigns at malls, primary health centers and blood banks in each of the five governorates of the State of Kuwait, and (iii) from visitors to our campaigns at Kuwait University, where students are enrolled from all the governorates. All participants were healthy and enrolled after obtaining written informed consent. The study protocol was approved by the Ethical Review Committee of the Dasman Diabetes Institute, Kuwait. Participant recruitment, sample collection, and related procedures were conducted in accordance with the tenets of the Declaration of Helsinki, as detailed elsewhere [1–3]. Each of the 620 individuals were assigned to subgroups (Kuwait-P, Kuwait-S and Kuwait-B) based on their surnames that inform their respective ancestral lineage i.e., Persian, Saudi Arabian Tribe, and Bedouin. The surname lineage classification was described in detail in our previous study [1].

#### **Genotyping and quality control**

All the 620 individuals were genotyped using HumanOmniExpress arrays for 730,525 SNPs (Illumina, Inc., San Diego, CA, USA) in accordance with the manufacturers' protocol. Quality control checks and data filtering were conducted using the PLINK (version 1.9) whole genome data analysis toolset [4]. The dataset was filtered to contain only autosomal SNPs with a genotyping success rate of >90%, a minor allele frequency of >5%, and a probability (*p*) value of >0.001 as determined using the Hardy–Weinberg exact test. Only samples with a genotyping success rate of >90% were included for analysis. To ensure that the study individuals are unrelated, we examined relatedness among them using the “–genome” feature in PLINK with the threshold PI\_HAT > 0.125 i.e., up to third degree relatives and randomly removed one sample per pair of related individuals. After QC and relatedness filtering, 583 individuals and 587,819 SNPs met the inclusion criteria for analysis (Supplementary Fig. 1). Genotype data has been deposited at the European Genome-phenome Archive (EGA), which is hosted by the European Bioinformatics

Institute (EBI) and the Centre for Genomic Regulation (CRG), under accession number EGAS00001005034.

## Datasets, merging, and phasing

We merged our data with the published genome-wide SNP genotype data of global populations (Supplementary Fig. 1 and Supplementary Table 1) available from the Estonian Biocentre database (<https://evolbio.ut.ee/>). The combined dataset was filtered using PLINK version 1.9 [4] to include only autosomal SNPs with a minor allele frequency of >1%, a genotyping success rate of >97%, and only individuals with a genotyping success rate of >95%. The filtered combined dataset, which included 2139 individuals and 244,688 SNPs, was phased using the SHAPEIT algorithm [5] and used for further analyses. To avoid the effects of markers with a strong linkage disequilibrium, we thinned the marker set by removing SNPs with an  $r^2$  value of >0.4 using a sliding window of 200 SNPs, shifted at intervals of 25 SNPs. The pruned dataset yielded 155,744 SNPs that were used for the relevant population genetics analyses, including Wright's  $F$ -statistic ( $F_{ST}$ ), principal component analysis (PCA), the ADMIXTURE tool for ancestry estimation, and runs of homozygosity (RoH).

## Population structure analyses: $F_{ST}$ , PCA, ADMIXTURE, and RoH

To explore the population genetic structure, we initially computed the mean pairwise  $F_{ST}$  differences between all population groups using the Weir and Cockerham method [6] implemented in PLINK version 1.9 [4]. Next, we conducted PCA of the linkage disequilibrium-pruned combined dataset using the smartpca program included with the EIGENSOFT software package version 6.1.4 [7,8]. Further, we ran an unsupervised structure-like analysis using the ADMIXTURE tool (version 1.3.0) [9] on the same dataset 25 times at different time intervals, with K values ranging from 2 to 12. Notably, K = 9 was the best supported K value as determined from the lowest cross-validation indexes. RoH was estimated using PLINK version 1.9 [4] with a sliding window of 100 SNPs (1000 kb), allowing for one heterozygous and five missing calls per window.

## Analyses to test admixture events and relative allele sharing: $f_3$ and $f_4$ statistics

We computed the  $f_3$  and  $f_4$  statistics using the *qp3Pop* and *qpDstat* programs (with  $f_4$  mode: YES) implemented in the ADMIXTOOLS software package [10]. A dataset containing 244,688 SNPs

and 2139 individuals was used for analyses of the  $f$ -statistics of modern individuals. The dataset of modern genomes was merged with that of ancient specimens, which contained a combined total of 231,418 SNPs and 3697 individuals. To measure the genetic similarity of different Kuwaiti groups (i.e., modern and ancient), we computed the derived allele sharing of the Kuwaiti population using outgroup  $f_3$  in the form of  $f_3(\text{Mbuti}; \text{Pop1}, \text{X})$ , where Pop1 is one of the three assigned groups of the Kuwaiti population, X is a modern or ancient West Eurasian population, and Mbuti is an outgroup (or Papuan to compare drift sharing between the Kuwait-B subgroup and other modern populations). Admixture  $f_3$  was also calculated to infer the plausible admixing sources in the history of the Kuwaiti population determined by negative  $f_3$  value with Z-score < -3 [10–12]. We calculated the  $f_4$  statistic to evaluate the level of gene flow between contemporary populations of Kuwaitis and their regional neighbors and allele sharing between modern Kuwaitis and available published data of ancient individuals from surrounding regions. The  $f_4$  statistic was applied to numerous population combinations in the form of  $f_4(\text{Pop1}, \text{Pop2}, \text{Pop3}, \text{Mbuti})$ , where Pop1 and Pop2 are two Kuwaiti groups to be compared, while Pop3 is a modern or ancient population from a relevant region.

We estimated the amount of Neanderthal ancestry present in the Kuwaiti subgroups using the  $f_4$ -ratio implemented in the ADMIXTOOLS package [10]. We computed the Neanderthal fraction using the  $f_4$ -ratio in the form  $f_4(\text{Altai}, \text{Chimp}, \text{Target}, \text{Dinka}) / f_4(\text{Altai}, \text{Chimp}, \text{Vindija}, \text{Dinka})$  following Petr et al. (2019) [13].

### **Haplotype-based fine-scale analyses: ChromoPainter and fineSTRUCTURE**

We used the phased dataset with 244,688 SNPs and 2139 individuals for haplotype-based analyses. The ChromoPainter tool, designed to identify haplotypes in sequence data, was used to "paint" each individual as a combination of all other sequences [14]. As a first step, we estimated the -n (recombination scaling constant) and -M (per site mutation rate) parameters by running the software's EM option on a small subset of populations and five randomly selected chromosomes (3, 7, 10, 17, and 22), as described elsewhere [15]. The estimated values for the two parameters were -n = 510.86 and -M = 0.00033. Then, we executed the ChromoPainter tool in the "All vs All" mode (using the -a flag), where all individuals are considered as both donors and recipients.

Next, we analyzed the resulting painted dataset using the fineSTRUCTURE algorithm [14] to identify genetically homogenous clusters. We first ran the software performing 2 million burn-

in iterations and 4 million MCMC iterations thinned every 10,000. This generated an MCMC file (.xml) that we used to build the tree structure using the option --T 1.

The analyzed individuals were initially classified into 233 clusters, which we reduced to increase the interpretability of subsequent analyses. More specifically, we iteratively “climbed the tree,” and the combined branches consisted of less than five clusters if at least one of them was composed of less than five individuals. The obtained tree was further refined by pooling together pairs or triplets of clusters if the pairwise total variation distance (TVD) based on the number of chunks shared among members of a branch was  $>0.035$ . After refinement, 40 clusters remained.

### **Non-negative least square (NNLS)**

Starting from the copying vectors obtained with the ChromoPainter tool, we reconstructed the ancestry profile of each cluster or individual by applying a slight modification of the NNLS function of R software version 3.5.1 (<https://www.r-project.org/>), as described elsewhere [15,16]. Therefore, for each individual belonging to a Kuwait cluster and for each of these clusters, we decomposed their ancestry as a mixture (with proportions summing to 1) of five (North/East Europe, Bedouins1, Yoruba, Druze, and North Africa clusters) and three (only North/East Europe, Bedouins1, and Yoruba) putative ancestral sources.

### **Exploring the variability of Kuwaiti individuals via pairwise TVD analysis**

To obtain a detailed picture of the variation underlying modern-day Kuwaiti population, we determined the pairwise TVD [16,17] among different individuals in specific clusters. TVD indicates the differences in ancestry profiles among individuals, where a high TVD value indicates high heterogeneity. First, we determined the TVD among individuals of the same cluster. Second, focusing only on Kuwaiti individuals, we determined the TVD among Kuwaitis and all the members of the respective clusters. Third, for each cluster, we determined the TVD only among Kuwaiti individuals. The analysis was performed in consideration of the number and length of genomic fragments inherited among individuals.

### **Estimation of admixture dates**

The times of admixture events were investigated using the GLOBETROTTER software [18]. We applied an “individual” approach by analyzing each Kuwaiti individual alone [19]. First, we

estimated the time of the admixture event by applying the prop.ind=1, null.ind=0 approach to the 583 target individuals. Then, we performed 20 bootstrap iterations with the following settings: prop.ind=0, bootstrap.date.ind=1, and num.admixdates.bootstrap=1. For each of the inferred admixture events, we considered only those that were characterized by bootstrap values for the time of an admixture event between 1 and 400.

We also computed a weighted LD statistic estimating the date of admixture using ALDER version 1.03 that model the decay of admixture LD [20] to validate the admixture events calculated by ALDER and GLOBETROTTER are consistent.
