## S2 Appendix. Estimating actuarial healthy life years (HLY) for each age year from abridged HLY tables

Notation:

*HLY*<sub>i</sub>: actuarial HLY for 5-year age groups i ( $i \in \{50 - 54,55 - 59, ... 80 - 84\}$ ), reported the Hungarian Central Statistical Office (HCSO) *HLY*'<sub>x</sub>: intermediate estimates of actuarial healthy life years for age *x HLY*<sub>x</sub>: estimated actuarial healthy life years for age *x* ( $x \in \{50,51, ... 84\}$ ) *HLY*<sub>85</sub>: estimated actuarial healthy life years for 85 years of age *mHLY*<sub>xi</sub>: mean *HLY*<sub>x</sub> in age group *i TH*'<sub>x</sub>: intermediate estimates of cumulative healthy years lived from year *x TH*<sub>x</sub>: estimated cumulative healthy years lived from year *x L*<sub>x</sub>: the number of persons who reached age *x*, reported by the HCSO *H*'<sub>x</sub>: intermediate estimates of healthy years for the cohort aged *x H*<sub>x</sub>: smoothed estimates of healthy years for the cohort aged *x H*<sub>x</sub>: intermediate conditional probability estimates of becoming limited in age *x* given being healthy in year *x*-1. ( $hq'_x < 1$ ) *hq*<sub>x</sub>: conditional probability estimates of becoming limited in age *x* given being healthy in year *x*-1. ( $0 < hq_x < 1$ )

Estimation procedure of  $HLY_x$ :

Step 1: we predicted  $HLY'_x$  by fitting a piecewise linear regression on  $HLY_i$  for age groups i ( $i \in \{50 - 54,55 - 59, ..., 80 - 84\}$ ) for both sexes using a spline of age as predictor with knots in age-group boundaries (e.g., 50, 55,80, 85).

## Healthy life year estimates for age years 50-84 in A) men and B) women

**Step 2:** by reversing calculations of the Sullivan method, from  $l_x$  of the life table, and  $HLY'_x$  from Step 1, we calculated  $TH'_x$  using the formula  $TH'_x = l_x * HLY'_x$ . **Step 3:** we calculated  $H'_x$  for each age x via  $H'_x = TH'_x - TH'_{x+1}$ .

**Step 4:** we obtained  $hq'_x$  by using the formula  $hq'_x = 1 - \frac{H'_x}{H'_{x-1}}$ . Since we identified negative  $hq'_x$  values, we considered  $H'_x$  estimates implausible.

Step 5: we estimated  $H_x$  by smoothing  $H'_x$  via a piecevise regression using the age spline of Step 1.

Cumulative cohort healthy life years  $(H_x)$  estimates for age years 50-84 in A) men and B) women

Step 6: we obtained  $TH_x$  by the formula  $TH_x = \sum_{n \ge x} H_n$ . Step 7: we obtained  $hq_x$  by using the formula  $hq_x = 1 - \frac{TH_x}{TH_{x-1}}$  and verified the plausibility of  $H_x$  estimates by observing for each  $hq_x$  that  $0 < hq_x < 1$ .

## Proportion becoming limited $(hq_x)$ , if being healthy in preceding year in A) men and B) women

**Step 8:** we obtained  $HLY_x$  via the Sullivan calculation using  $H_x$  from Step 5:  $HLY_x = \frac{\sum_{n \ge x} H_n}{l_x}$ .

**Step 9:** we estimated  $HLY_{85}$  as follows: since  $HLY_i$  represents the average healthy life expectancy for the entire 85+ age-group ( $HLY_{85+}$ ), assuming that  $HLY_{85} = HLY_{85+}$  would underestimate healthy life expectancies in all ages x≥85 years. Therefore, we used  $HLY_{85} = HLY_{85+} + d$  in the model and determined *d* via numeric optimisation so that the squared difference between  $HLY_i$  and  $mHLY_{xi}$  was set to minimum.

Healthy life years by 5-year age groups ( $HLY_i$ ) and means of yearly healthy life year estimates by 5-year age groups ( $mHLY_{xi}$ ) in A) men and B) women

Step 10: we obtained  $HLE_x = HLY_x + x$  for all ages x from 50 to 85 years.
