The true impact of SARS-CoV-2 in Africa, the continent that has most people living with HIV (PLWH), is still unclear. To date just over 7.5 million cases and 189,000 deaths have been reported from sub-Saharan Africa. These numbers are far below those reported in high-income countries such as the USA and UK (<https://africacdc.org/covid-19>, accessed 23 August 2021). Several factors have been proposed for the geographic variation in the impact of the virus including differences in population age distribution, underlying host genetic and immunological mechanisms ^[1], environmental factors ^[2], limited testing capacity in resource-poor settings, and underreporting due to stigma ^[3, 4]. Of particular importance is the impact of infectious comorbidities such as HIV, malaria, and tuberculosis. The impact of HIV on SARS-CoV-2 infection and disease course is of specific interest because HIV infection is lifelong and associated with generalized immunodeficiency which may influence clinical outcomes ^[5]. Moreover, HIV may alter immune responses to some pathogens and vaccines, with implications for health, and for diagnostic or surveillance algorithms that rely on immune biomarkers.

In this issue of *AIDS*, Crowell *et al.* ^[6] retrospectively screened blood samples from cohort participants collected prior to the first known case of COVID-19 in Kenya for anti-SARS-CoV-2 nucleocapsid IgM, IgA and/or IgG antibodies using a commercial kit. In total, 19 (3.3%) participants had detectable levels of total antibodies with no difference in antibody responses between participants with and without HIV. PLWH in this study were all virally suppressed. Further investigations demonstrated seven of these participants had a prior positive test since June 2019, pre-dating the COVID-19 pandemic. The authors

therefore concluded that positive antibody responses could either be due to cross-reactivity or asymptomatic infections. This study highlights two important points; 1) the effect pre-exposure to other human coronaviruses (HCoVs) might have on SARS-CoV-2 infection and disease course and 2) the possibility of cross-reactivity when performing diagnostic testing or surveillance for SARS-CoV-2 using immunoassays.

The presumed lower morbidity and mortality in Africa may be multifactorial but so far, preexisting cross-reactive immunity from other HCoVs or other circulating viruses cannot be ruled out [7–10]. Pre-existing IgG cross-reactivity to SARS-CoV-2 S and N proteins in individuals uninfected and unexposed to the SARS-CoV-2 have been widely reported [9, 11, 12]. Pre-exposure and cross-reactivity due to circulating HCoVs have been hypothesized to modify SARS-CoV-2 infection outcomes by decreasing disease severity. The latter could also partially explain the age distribution of COVID-19 disease severity as HCoV infection rates are higher in children than in adults and correlates with relative protection from COVID-19 disease [13]. Understanding preexisting immunity will be critical to elucidate susceptibility to SARS-CoV-2 infection in Africa as well as the natural course of disease. Further, identifying conserved cross-reactive epitopes in HCoV or other mechanisms could prove beneficial for development of a universal vaccine or immune-based therapies.

On the other hand, cross-reactivity caused by seasonal coronaviruses may result in incorrect or false positive results when immunoassays are used for diagnostics or sero-surveillance [14, 15]. Several community-based and population-based sero-surveys in Africa have demonstrated seroprevalences ranging from 8.8 to 60.6% [8, 16–18], sometimes much higher than reported case data would suggest to be the true prevalence. Interestingly, recent studies on the cross-reactivity of SARS-CoV-2 and other HCoVs demonstrated significantly higher cross-reactivity in sub-Saharan Africa compared to the USA [7, 18]. Similar results were reported by Tso *et al.* [7] where a significant cross-reactivity with the N-protein was observed while no differences were reported against the S protein. Anti-SARS-CoV-2 S1-RBD antibodies have also been shown to have a higher sensitivity versus N protein antibodies for both acute and post-infection phases with the anti-N IgG antibodies waning after acute infection [7, 19]. These data suggest that immunoassays to estimate seroprevalence versus diagnostics may require fine-tuning, including careful consideration of viral protein targets [20].

Considering the high prevalence of HIV in some communities, particularly in south and eastern Africa, it is important to understand its potential implications for health, diagnostics and surveillance related to the SARS-CoV-2 virus. Data suggest that individuals with advanced HIV, low CD4+ T-cell counts, and a high HIV viral load are more at risk for severe COVID-19 outcomes compared to antiretroviral therapy (ART) controlled HIV and that these individuals should be prioritized for SARS-CoV-2 vaccination [21–25]. However, studies have reported similar humoral immune responses between PLWH on ART and HIV uninfected individuals [26, 27]. Given that individuals with suppressed HIV are less likely to suffer severe disease outcomes, focus should turn towards the impact that COVID-19 has on access to treatment and care for PLWH, and the impact of non-ART-controlled HIV infection on COVID-19 [23]. A recent global cross-sectional survey reported that

18% of men who have sex with men were either unable to refill or access their ART prescriptions [28] inevitably resulting in an increased viral load and low CD4+ T-cell count. Persistent SARS-CoV-2 infection has also been reported in immune-compromised individuals such as PLWH that do not have ART-controlled infection. These individuals should be considered during sero-surveillance studies as they may not reliably develop anti-SARS-CoV-2 antibody responses [29]. Therefore, implementing a combined use of molecular and serological testing will be necessary for continued surveillance [20]. A cause for concern is the increasing reports that prolonged viral replication and intrahost evolution in immunocompromised persons are contributing to the emergence of new variants capable of immune escape [30–34]. Superinfections in immunocompromised, persistently infected individuals have also been reported resulting in adverse clinical outcomes [35, 36].

In conclusion, preexisting immunity to HCoVs may need to be further investigated as one potential mechanism underlying the lower prevalence and severity of SARS-CoV-2 infection in certain geographic areas in Africa. Further, comparative seroprevalence and serosurveillance studies that rely on immune assays need to be designed and interpreted with caution, considering the specific or unique epidemiological characteristics, particularly those related to HCoVs population dynamics and SARS-CoV-2 persistent infections, as these factors may influence assay sensitivity and specificity within regions. A research gap exists in addressing the impact of infectious comorbidities on SARS-CoV-2 infection outcomes, particularly conditions prevalent in LMICs such as HIV. The impact of HIV on SARS-CoV-2 infection trajectory is incompletely understood but evidence suggests that uncontrolled HIV negatively impacts SARS-CoV-2 clinical outcomes, and the pandemic has impeded healthcare access for PLWH. COVID-19 vaccinations should therefore be prioritized for PLWH especially for individuals with poorly controlled HIV while African countries with low vaccination coverage should ameliorate vaccine campaigns.
