Abstract

Background: No study on the long-term incidence of Alzheimer’s disease (AD) and related dementias (ADRD) has been reported in women with breast cancer by vascular diseases.

Objective: To determine the risk of ADRD in association with cardiovascular diseases (CVD), stroke, hypertension, and diabetes in women with breast cancer.

Methods: Study identified 246,686 women diagnosed with breast cancer at age ≥ 65 years in 1991–2015 from the Surveillance, Epidemiology, and End Results (SEER)-Medicare linked database. Women were free of ADRD at the time of cancer diagnosis and followed from 1991 to 2016.

Results: Cumulative incidence of AD over 26 years of follow-up varied from 10.7% to 13.6% by CVD, stroke, hypertension, and diabetes. Cumulative incidence of ADRD was higher in those with CVD (40.75%) versus no-CVD (31.32%), stroke (40.24%) versus no-stroke (31.34%), hypertension (33.06%) versus no-hypertension (30.47%), and diabetes (33.38%) versus no-diabetes (31.77%). After adjusting for confounders, those with CVD (hazard ratio:1.30, 95%CI: 1.27–1.33), stroke (1.50,1.47–1.54), hypertension (1.08,1.06–1.09), and diabetes (1.26,1.24–1.29)

SUPPLEMENTARY MATERIAL

The supplementary material is available in the electronic version of this article: <https://dx.doi.org/10.3233/JAD-215657>.

had significantly higher risks of developing ADRD. Women aged 80–84, and 85 had 5- and 7-fold higher risks of AD than those aged 65–69. As compared to white women, black women had a significantly higher risk of AD (1.21, 1.16–1.27), whereas Asians/Pacific-Islanders had a significantly lower risk of AD (0.77, 0.71–0.83).

Conclusion: In women with breast cancer, CVD, stroke, hypertension, and diabetes were associated with a significantly higher risk of developing any ADRD combined. The risk of ADRD was higher in black women and lower in Asian/Pacific-Islanders than white women.

Keywords

Alzheimer's disease; breast cancer; dementias; medicare; vascular diseases

INTRODUCTION

The prevalence of Alzheimer's disease (AD) and related dementias (ADRDs) has been increasing over the past few decades [1–6] and is projected to be doubled by 2025 and tripled by 2050 [1–5]. The global number of individuals who live with dementia increased from 20.2 million (95% uncertainty interval: 17.4–23.5) in 1990 to 43.8 million (37.8–51.0) in 2016 [6]. In the United States, it is estimated that 5.8 million Americans of all ages live with AD in 2019, of which 5.6 million people (97%) are age 65 and 81% are age 75 [1–4]. AD is the 6th leading cause of death in the United States [1–3] and is still incurable although much progress has been made [1–3].

Etiologies for ADRD remained largely unknown, but they have been linked to a number of risk, history of psychiatric disorders, head trauma, genetic factors, and vascular diseases or related risk factors such as cardiovascular diseases (CVD), stroke, hypertension, and diabetes [1–11]. Numerous studies have documented that regular physical exercise and good management of cardiovascular risk factors (such as diabetes and hypertension) are associated with a reduced risk of cognitive decline and may be associated with a reduced risk for dementia [1–3, 9].

To the best of our knowledge, no study on the long-term incidence of ADRD has been reported in older women with breast cancer amongst Medicare beneficiaries. Because of early detection and significant improvements in treatment for breast cancer, women diagnosed with breast cancer now have higher survival rates. It would be of great interest to know the likelihood of developing ADRD later in their life among those breast cancer survivors. It is also imperative to examine whether common comorbid conditions (CVD, stroke, hypertension, and diabetes) affect the risk of ADRD when compared to those without these comorbidities. Therefore, this study aimed to determine the risk of AD and ADRD in association with cardiovascular disease, stroke, hypertension, and diabetes in a large cohort of women with breast cancer with up to 26 years of follow-up from 1991 to 2016. Our hypothesis was that in women with breast cancer, the risk of ADRD is significantly higher in patients who had a history of CVD, stroke, hypertension, and diabetes than those who did not.

METHODS

Data sources

This study used the de-identified Surveillance, Epidemiology, and End Results (SEER) and Medicare-linked database for breast cancer cases between 1991 and 2015 with follow-up from 1991 to 2016. The SEER program, supported by the National Cancer Institute (NCI), includes 17 population-based tumor registries in 8 states (Connecticut, Iowa, New Mexico, Utah, Hawaii, Kentucky, Louisiana, New Jersey), 7 metropolitan/rural areas (San Francisco/Oakland, Detroit, Atlanta, Seattle, Rural-Georgia, Los Angeles County, and San Jose-Monterey areas), Greater-California, and Greater-Georgia. The Medicare program provides payments for hospital, physician, and outpatient medical services for > 97% of persons aged ≥ 65 [12, 13]. The Committee for the Protection of Human Subjects at the University of Texas Health Science Center at Houston approved this study.

Study population

The study population consisted of 332,532 women who were diagnosed with breast cancer at age ≥ 65 years from 1991 through 2015 (Fig. 1). The study excluded those who did not have a full coverage of both Medicare Part A and Part B or who were enrolled with Health Maintenance Organizations from the date of diagnosis to the date of death or the date of last follow-up on December 31, 2016. The study excluded those who died within 30 days of breast cancer diagnosis and those who had a history of any dementias (ADRD) within 365 days prior to or within 30 days of cancer diagnosis. After exclusions, 246,686 women with breast cancer who were free of ADRD at the baseline were left in the final analysis.

Study variables

Main exposures—Main exposure variables are CVD (including myocardial infarction, congestive heart failure, or peripheral vascular disease), stroke, hypertension, and diabetes, which were defined as having an ICD-9 or ICD-10 diagnosis within 12 months prior to or 30 days after the date of cancer diagnosis (Supplementary Table 1).

Covariates—Covariates include socio-demographics (age, race/ethnicity, marital status), tumor factors (stage, size, grade, hormone receptor status, and receipt of chemotherapy and radiation therapy), comorbidity, year of diagnosis, and SEER areas. Comorbidities included chronic pulmonary disease, congestive tissue disease, ulcer disease, mild liver disease, hemiplegia, moderate or severe renal disease, leukemia, moderate or severe liver disease, and human immunodeficiency virus (HIV+) or acquired immune deficiency syndrome (AIDS). These co-existing conditions were identified through diagnoses or procedures in Medicare claims made within 1 year prior to and 30 days after the date of cancer diagnosis based on the NCI's comorbidity coding program [14]. Each comorbid disease was weighted according to its severity and the sum of all scores was analyzed as 0, 1, and ≥ 2 [14].

Main outcomes—Main outcome variable was the incidence of ADRD. ADRD was defined if there was a diagnosis (ICD-9 or ICD-10) for any specific type of dementias (Supplementary Table 2). We used two approaches to define ADRD: 1) all diagnosis codes (from the first diagnosis code to the 12th diagnosis code available in Medicare claims)

and 2) primary diagnosis code only (i.e., first diagnosis code). ADRD was classified into 6 specific types of dementias: AD, vascular dementia, dementia with Lewy bodies (Lewy), frontotemporal degeneration and dementias (FTD), mild cognitive impairment (MCI), and other dementias that were not included in the previous 5 categories.

Analysis—Differences in the distribution of baseline characteristics among breast cancer patients with CVD, stroke, hypertension, and diabetes were tested using the chi-square statistics. Cumulative incidence of ADRD is defined as the ratio of the number of cases with a new dementia over the number of population at risk who were free of dementia at the baseline when a breast cancer diagnosis was made. Incidence density is defined as the ratio of the number of cases with a new dementia over the total number of person-years by taking into consideration the different follow-up times of study participants. Person-years are calculated as the number of people multiplied by the number of years from the time of breast cancer diagnosis to the date of first dementia, or date of death, or date of last follow-up (December 31, 2016), whichever occurred first. Cox regression models were utilized to perform the time to event analysis to determine the risk of developing dementia by vascular diseases while adjusting for potential confounders. The proportionality assumption was assessed by checking whether the log-log Kaplan-Meier curves were parallel and did not intersect and also by adding an interaction term between exposures and time variables to the Cox models [15, 16]. Fine and Gray competing risk proportional hazards regression was performed accounting for death as a competing risk [16].

RESULTS

Table 1 presents the distribution of baseline characteristics by the status of CVD, stroke, hypertension, and diabetes. Older women had a higher prevalence of CVD, stroke, and hypertension, but diabetes status was more evenly distributed by age. For example, the percentage of women who had CVD was 22.7% for age ≥ 85 and 14.7% for age 65–69, whereas the percentage of women who did not have CVD was 11.1% for age ≥ 85 and 28.4% for age 65–69. African American women and unmarried women appeared to have higher percentages of these vascular diseases. Women with advanced tumor stage, larger size, poorer grade, and hormone receptor negative tumors had a slightly higher prevalence of vascular diseases. As expected, patients who received chemotherapy or radiation therapy were less likely to have vascular diseases and those with higher comorbidity scores had a high percentage of these vascular diseases. There were some variations by years of diagnosis and by geographical areas in SEER.

Table 2 presents the cumulative incidence rates of AD, other specific types of dementias, and overall combined ADRD in a large cohort of women who were diagnosed with breast cancer and were free of ADRD at baseline (or at the time of cancer diagnosis) by the status of CVD, stroke, hypertension, diabetes, age, and other factors. The cumulative incidence of AD over the 26 years of follow-up varied from 10.7% to 13.6% by CVD, stroke, hypertension, and diabetes (second column in Table 2), whereas the cumulative incidence of AD as primary diagnosis only varied from 5.8% to 7.7% (in Supplementary Table 3). The cumulative incidence of any ADRD combined (last column in Table 2) was higher in those with CVD (40.75%) than those without CVD (31.32%), stroke (40.24%) than those

without stroke (31.34%), hypertension (33.06%) than those without hypertension (30.47%), and diabetes (33.38%) than those without diabetes (31.77%).

Table 3 presents the incidence density of ADRD by taking into consideration differential follow-up times of women with breast cancer. The number of ADRD cases per 1,000 person-years were higher in those with CVD, stroke, hypertension, and diabetes than their counterparts. Tables 2 and 3 also present the cumulative incidence and incidence density rates of ADRD by age, race/ethnicity, tumor characteristics, comorbidity scores, chemotherapy, radiation therapy, and SEER areas. For example, the cumulative incidence of AD in women aged 65 with breast cancer and with up to 26 years of follow-up increased from 5.02% for age 65–69 to 9.42% for age 70–74, 14.32% for age 75–79, and over 18% for age 80. The cumulative incidence of all ADRD increased from 17.67% for age 65–69 to 26.97% for age 70–74, 37.21% for age 75–79, and over 45% for age 80.

Table 4 presents the time to event hazard regression analyses after adjusting for potential confounders. Those with CVD (hazard ratio: 1.30, 95% CI: 1.27–1.33), stroke (1.50, 1.47–1.54), hypertension (1.08, 1.06–1.09), and diabetes (1.26, 1.24–1.29) had significantly higher risks of developing any ADRD combined (last column in Table 4). In terms of 6 specific types of dementias, CVD was associated with a significantly higher risk of AD, vascular dementia, and other dementias, was associated with a significantly decreased risk of MCI, but was not significantly associated with the risk of Lewy dementia and FTD. Stroke was associated with a significantly increased risk of AD, vascular dementia, Lewy dementia, MCI, and other dementias, but was not significantly associated with the risk of FTD. Hypertension was associated with a significantly lower risk of AD and vascular dementias and was not significantly associated with the risk of Lewy dementia and FTD but was associated with a significantly higher risk of MCI and other dementias. Diabetes was associated with a significantly higher risk of AD, Lewy dementia, MCI, and other dementias, but was not significantly associated with vascular dementia and FTD.

The risk of AD, non-AD dementias, and any ADRD all increased significantly with age. For example, the risk of AD was 1.94 (95% CI: 1.86–2.02) for age 70–74, 3.26 (3.13–3.40) for age 75–79, 5.29 (5.07–5.52) for age 80–84, and 7.42 (7.08–7.78) for age 85 as compared to those aged 65–69. As compared to white women, black women with breast cancer had a significantly higher risk of AD (1.21, 1.16–1.27) and any ADRD combined (1.16, 1.13–1.19), whereas Asians/Pacific Islanders had a significantly lower risk of AD (0.77, 0.71–0.83) and any ADRD combined (0.83, 0.79–0.86). Those unmarried women or those with unknown marital status had a significantly higher risk of AD and ADRD than those married women with breast cancer. The more advanced tumor stage, larger tumor size, poorer tumor grade, and negative hormone receptor status appeared to be associated with a small but significantly increased risk of AD and ADRD combined. Those who received chemotherapy and radiation therapy had a lower risk of AD and ADRD. The higher comorbidity scores were significantly associated with a higher risk of AD, MCI, other dementias, and ADRD combined. There were also some geographic variations in the risk of AD and ADRD, in which women from Connecticut, Detroit, Hawaii, and Kentucky had a significantly higher risk of AD and ADRD, while women from Iowa, Seattle, Utah, and Louisiana had a significantly lower risk of AD and ADRD as compared to women from California.

Table 5 presents the risk of different types of dementia in association with the number of vascular diseases (CVD, stroke, hypertension, and diabetes), which were classified into none of these diseases present or any 1, 2, 3, or 4 diseases present. As compared to women without any of these 4 diseases, those with any 2 or more of these diseases were significantly more likely to develop all types of dementias, including AD, vascular dementia, and total ADRD. Women with only one of these diseases present did not have a significantly increased risk of AD and vascular dementia but had a significantly higher risk of other types of dementia and total ADRD. There appears to be a dose-response relationship between the risk of ADRD and the number of vascular risk factors present. The point estimates for the risk of ADRD increased with the number of vascular diseases present. For example, the risk of ADRD increased from 1.14 (1.12–1.16) to 1.46 (1.43–1.49), 1.90 (1.84–1.96), and 2.47 (2.30–2.66) respectively for 1, 2, 3, and 4 vascular diseases present. Moreover, their 95% confidence intervals did not overlap,

The incidence rates and the adjusted risk of AD, non-AD dementias and ADRD combined as primary diagnosis only (Supplementary Tables 3–5) had the similar patterns by CVD, stroke, hypertension, diabetes, and other sociodemographic and tumor characteristics as the above results using any diagnosis code for ADRD. After taking into consideration death before ADRD as a competing risk in the Fine and Gray regression models, the risk of ADRD and other dementias were still significantly higher in women with CVD, stroke, hypertension, and diabetes, while the risk of AD remained significantly higher in women with stroke and significantly lower in women with hypertension, but the risk of AD was no longer significantly different in women with CVD or diabetes from those without CVD or diabetes. The risk of AD and ADRD by age, race/ethnicity, and other tumor factors remained similar without much changes. There were no significant interactions between chemotherapy and any of these four diseases (CVD, stroke, hypertension, and diabetes) on the risk of ADRD.

MCI can be a preclinical or prodromal stage of ADRD. It can also improve and stabilize. It is interesting and important to see the results on the risk of ADRD with and without including MCI. Hence, sensitivities analyses were performed by excluding MCI from the total ADRD. Supplementary Table 6 presents the 10-year and 26-year cumulative incidence rates of AD and ADRD by including MCI versus excluding MCI. As expected, the 26-year cumulative incidence of ADRD by excluding MCI (31.68%) was slightly lower than the incidence of ADRD that included MCI (32.14%). The 10-year cumulative incidence rate in women with breast cancer was 9.79% for AD, 27.88% for ADRD excluding MCI, and 28.31% for ADRD including MCI. The 10-year cumulative incidence rate of ADRD excluding MCI was higher in those with CVD than those without (38.71% versus 26.84%), and was the same for stroke (38.83% versus 26.79%), hypertension (29.84% versus 24.32%), and diabetes (31.11% versus 26.90%). The 10-year and 26-year cumulative incidence rates of AD and ADRD increased significantly with age and varied by other factors, which were similar to those found in Tables 2 and 3 above. Overall, excluding MCI did not materially change the study conclusions regarding the effects of vascular risk factors on the risk of ADRD in breast cancer survivors.

Supplementary Table 7 presents the adjusted 10-year and 26-year risk of AD and ADRD by including or excluding MCI. The 10-year and 26-year risk of both AD and ADRD regardless

of including or excluding MCI was significantly higher in those with CVD, stroke, and diabetes than those without a history of these diseases, after adjusting for other confounding factors. For example, the 10-year risk of AD (1.32, 1.26–1.37), ADRD including MCI (1.51, 1.47–1.54), and ADRD excluding MCI (1.50, 1.47–1.54) was significantly higher in those with stroke than in those without stroke. Similarly, the 26-year risk of AD (1.32, 1.27–1.37), ADRD including MCI (1.50, 1.47–1.54), and ADRD excluding MCI (1.50, 1.47–1.53) was significantly higher in those with stroke than in those without stroke. Patients with hypertension had a significantly higher 10-year risk of total ADRD including MCI (1.07, 1.05–1.09) and ADRD excluding MCI (1.07, 1.05–1.08) and had a significantly higher 26-year risk of total ADRD including MCI (1.08, 1.06–1.09) and ADRD excluding MCI (1.07, 1.06–1.08) than those without hypertension. The 10-year risk (0.93, 0.91–0.96) and 26-year risk (0.96, 0.93–0.98) of AD were slightly but significantly lower in those with hypertension than those without hypertension (Supplementary Table 7).

Supplementary Table 8 presents the risk of AD, other specific types of dementias, and total ADRD in association with different types of CVD (myocardial infarction, congestive heart failure, and peripheral vascular disease), stroke, hypertension, and diabetes in an entire cohort of women, and in stratified cohorts by age group (< 75 and ≥ 75 years). Myocardial infarction was not significantly associated with the risk of AD, vascular dementia, dementia with Lewy bodies, FTD, and MCI, but was associated with a significantly higher risk of other dementias and total ADRD. Congestive heart failure and peripheral vascular disease were significantly associated with an increased risk of AD, vascular dementia, other dementias and total ADRD; were associated with a significantly lower risk of MCI, but were not significantly associated with the risk of dementia with Lewy bodies and FTD. Furthermore, interactions between age (< 75 and ≥ 75 years) and vascular diseases (myocardial infarction, stroke, hypertension, and diabetes) on the risk of AD, vascular dementia, and total ADRD were statistically significant ($p < 0.05$). Interactions between age (< 75 and ≥ 75 years) and congestive heart failure or peripheral vascular disease were significant only for the risk of total ADRD but not significant for the risk of AD and vascular dementia.

In stratified analyses by age, myocardial infarction was significantly associated with an increased risk of AD (1.25, 1.10–1.43), vascular dementia (1.27, 1.00–1.62), other dementias (1.23, 1.14–1.32), and total ADRD (1.22, 1.14–1.31) in women aged < 75 years. In contrast, the association between myocardial infarction and the risk of different types of dementias and total ADRD in those aged ≥ 75 or older was similar to that of the entire cohort of women. Stroke was associated with a significantly higher risk of all types of dementias in both young (< 75 years) and older women (≥ 75 years). Hypertension, however, was associated with a significantly higher risk of AD and vascular dementia in women < 75 years but was associated with a significantly decreased risk of AD and vascular dementia in older women aged ≥ 75 years. Hypertension was associated with a significantly higher risk of MCI, other dementias and total ADRD, but was not associated with the risk of dementia with Lewy bodies and FTD in both age groups. Diabetes, on the other hand, was associated with a significantly higher risk of all types of dementias in both young (< 75 years) and older women (≥ 75 years), but there was no significant association between diabetes and the risk

of FTD in women aged < 75 years and the risk of vascular dementia in women aged 75 years.

DISCUSSION

This study examined the long-term risk of AD, specific types of non-AD dementias, and all ADRD combined in association with CVD, stroke, hypertension, and diabetes in a large cohort of women diagnosed with breast cancer. The study found that CVD, stroke, hypertension, and diabetes were associated with a significantly higher risk of developing any ADRD combined. However, the risk of 6 specific types of dementias differed by CVD, stroke, hypertension, and diabetes. The CVD, stroke, and diabetes were associated with a significantly higher risk of AD, whereas hypertension was associated with a significantly lower risk of AD in this large cohort of older women aged 75 years. As expected, the risk of AD, non-AD dementias, and any ADRD all increased significantly with age. Women aged 70–74, 75–79, 80–84, and 85 had 2-, 3-, 5-, and 7-fold higher risks of AD, respectively, as compared to those women aged 65–69 year.

The Framingham Heart Study [1, 7] reported that the estimated lifetime risk of any ADRD and only AD at age 65 was 24.6% and 21.1% for women, and 15.5% and 11.6% for men. Our study shows that the risk of any ADRD over 26 years of follow-up in older women with breast cancer at age 65 was 31.79% and the risk of only AD was 11.77%. The risk of ADRD in women with breast cancer at age 65 was higher than the lifetime risk for ADRD in Framingham women at age 65, but the risk of only AD in women with breast cancer at age 65 was lower than the lifetime risk for AD in women at age 65 from Framingham study [1, 7]. However, these comparisons might not be ideal between the Framingham community-based general population [7] and the current cohort of women who were diagnosed with breast cancer in SEER areas, but the information is critical for the estimated risk of ADRD and AD and should stimulate further investigations to see whether or why there is a gap among different populations. Several studies showed an inverse relationship between cancer and AD [17–19] or ADRD [20] and that the risk of AD dementia in persons with cancer could be reduced by 35% [18]. A recent systematic review and meta-analysis of 19 cohort studies and 3 case-control studies concluded that there was an inverse association between cancer and AD dementia, which was not likely attributable to diagnostic bias, competing risk bias, or inappropriate control for potential confounding factors [19].

Many previous studies also showed that the risk of ADRD was higher in those with vascular diseases. For example, patients with heart failure performed worse in neuropsychological testing than those healthy individuals and those with CVD, stroke, and hypertension also had a higher risk of dementia [8–11], whereas diabetes was shown to directly or indirectly affect the risk of ADRD as it is major risk factor for CVD, stroke, and hypertension. Numerous studies have documented that good management of cardiovascular risk factors (such as diabetes, obesity, smoking, and hypertension) is associated with the reduced risk of cognitive decline and may be associated with the reduced risk of dementia [8–11, 21, 22]. Interestingly, our study showed that hypertension in older women with breast cancer was associated with a significantly lower rather than higher risk of AD. It is unclear if this was

due to breast cancer as discussed above for the association between cancer and ADRD, or due to older age in this cohort. The association between hypertension and ADRD became more complicated in mid-age versus older population. Many studies explored the complex relationship between hypertension and ADRD [23–25] and some found that hypertension at midlife is a risk factor for ADRD but hypertension at late life may have no effect or a weak protective effect for ADRD [23–25]. A number of studies, including a meta-analysis of longitudinal studies, showed that mid-life hypertension rather than late-life hypertension was a risk factor for AD [23–25]. Similarly, a comprehensive review concluded that the evidence on the association between treatment of hypertension in the elderly and the risk of dementia was inconclusive [26]. Although a recent large trial showed that intensive blood pressure control may be associated with a reduced risk of MCI [27], it is still unclear whether the risk of late stage of dementias such as AD will be decreased significantly. Our current study cannot answer this question directly, but it certainly raises an important research question for future research endeavor.

This study has a number of strengths. First, the study examined a large nationwide, population-based cohort of women with breast cancer aged ≥ 65 from the SEER areas, accounting for 26% of the U.S. population. Because ADRD takes a long time to develop, is relatively rare in young population, and is uncommon at the early stage of study follow-up, a very large study population is often required in order to generate meaningful information on the true incidence of ADRD and on potential risk factors associated with it. This large cohort of women, diagnosed with breast cancer in 1991–2015, has been followed up for up to 26 years, making this study unique and significant. Second, this study used the national comprehensive insurance program (Medicare) claims data to capture the incidence of AD and ADRD. Medicare is a federal health insurance program created in 1965 covering people aged ≥ 65 , regardless of income, medical history, or health status. Medicare data are the lifelong medical records for these beneficiaries from the time of enrollment to the time of death regardless of where they seek medical care or services across the country, hence providing the most comprehensive lifetime history of medical records. Third, a large cohort of women with breast cancer were identified from the most authoritative cancer data source in NCI's SEER program. SEER not only has a high complete case ascertainment rate, but also has high-quality information on tumor characteristics such as stage, size, and grade. Fourth, vascular diseases and comorbid conditions in women with breast cancer can be identified reliably from Medicare claims data which have been well validated for comorbidities in cancer patients [28–30].

This study also has a few limitations. First, because information on the history of CVD, stroke, hypertension, and diabetes relied on Medicare claims at baseline when breast cancer diagnosis was made, completeness and duration of these conditions as well as their treatment and control overtime are unknown, which could potentially affect the risk of ADRD. Second, although several studies [28–30] showed that Medicare claims data generally suggest a sensitivity of about 85% for overall dementia, there could be a certain degree of misclassification. It is possible that ADRD may be overestimated and AD only may be underestimated or misclassified in using Medicare claims data, which might explain the higher risk of ADRD and lower risk of AD only in our study cohort of women with breast cancer than the lifetime risk for ADRD and AD only in women from Framingham

[1, 7]. Third, the study population only included elderly women with breast cancer aged 65. Therefore, the findings from this study may not be generalizable to younger patients. However, most ADRDs, hypertension, diabetes, and cancer occur in older persons (> 65 years), so the findings will still be generalizable to a larger population. Finally, the study cannot capture all relevant variables and there is a lack of information on factors such as smoking or family history, which might affect the risk of ADRD.

In conclusion, the study found that in a large cohort of women diagnosed with breast cancer at age ≥ 65 with up to 26 years of follow-up from 1991 to 2016, the overall patterns on the risk of ADRD and its association with vascular diseases and socio-demographic factors are consistent with the findings of previous studies, although the magnitude varied by the types of risk factors and types of ADRD. CVD, stroke, hypertension, and diabetes were associated with a significantly higher risk of developing any ADRD combined. The risk of 6 specific types of dementias differed by CVD, stroke, hypertension, and diabetes. CVD, stroke, and diabetes were associated with a significantly higher risk of AD, whereas hypertension was associated with a significantly lower risk of AD in those aged ≥ 75 years. The risk of ADRD significantly increased with age, was higher in unmarried women, and varied by race/ethnicity with a higher risk in black women and a lower risk in Asians/Pacific Islanders as compared to white women. Further studies may be needed to explore the effect of breast cancer on the risk of ADRD in a cohort of cancer patients when comparing it with women with similar background risk, but without breast cancer, and to examine whether and how the treatment for vascular diseases affect the risk of AD and non-AD dementias.

Supplementary Material

ACKNOWLEDGMENTS

This study was supported by the grants (numbers R01AG067498 and R01AG058971) from the National Institute on Aging (NIA) of the National Institutes of Health (NIH), USA. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH/NIA.

We acknowledge the efforts of the National Cancer Institute (NCI), Centers for Medicare and Medicaid Services (CMS), Information Management Services (IMS), and the Surveillance, Epidemiology, and End Results (SEER) registries in the creation of this SEER-Medicare linked database.

DATA SHARING

The National Cancer Institute's SEER (Surveillance, Epidemiology, and End Results)-Medicare Data User Agreement (DUA) specifically requests that "You (the Investigators) will not permit others to use the data except for collaborators within your institution involved with the research as described in your proposal". However, the SEER-Medicare linked data are available to researchers from the National Cancer Institute upon signing the DUA, having the study proposal approved, and paying the related costs, which is available in their website: <https://healthcaredelivery.cancer.gov/seermedicare/>. We plan to share the statistical models and statistical programs that we used to analyze these data upon request and to share study findings and related study resources. We also plan to make results and algorithms available for verification or replication by other researchers.
