Abstract

Treatment of dentin hypersensitivity with oxalates is common, but their efficacy remains unclear. Our objective was to systematically review clinical trials reporting an oxalate treatment compared to no treatment or placebo with a dentin hypersensitivity outcome. Risk-of-bias assessment and data extraction were performed independently by two reviewers. Standardized mean differences (SMD) were estimated using random-effects meta-analysis. Of 677 unique citations, 12 studies with high risk-of-bias were included. The summary SMD for 3% monohydrogen-monopotassium oxalate (n=8 studies) was -0.71 [95% Confidence Interval: $-1.48, 0.06$]. Other treatments, including 30% dipotassium oxalate (n=1), 30% dipotassium oxalate plus 3% monohydrogen monopotassium oxalate (n=3), 6% monohydrogen monopotassium oxalate (n=1), 6.8% ferric oxalate (n=1) and oxalate-containing resin (n=1), also were not statistically significant different from placebo treatments. With the possible exception of 3% monohydrogen monopotassium oxalate, available evidence currently does not support the recommendation of dentin hypersensitivity treatment with oxalates.

Keywords

dentin sensitivity; oxalates; systematic review; meta-analysis

INTRODUCTION

Dentin hypersensitivity (DH) is defined as brief, sharp pain elicited when dentin is exposed to thermal, tactile, osmotic, chemical, or evaporative stimuli (Canadian Advisory Board on Dentin Hypersensitivity, 2003). Most data to-date support a theory that these stimuli induce fluid flow within dental tubules, which triggers baroreceptors near the pulp, leading to pain (Pashley, 1994). This so-called hydrodynamic theory of pain generation assumes an exposed dentin surface and patent tubules that allow fluid flow to reach the pulp where the baroreceptors reside (Brannstrom et al., 1967). Up to 40 million American adults report DH symptoms each year (Addy, 1990), but reported prevalence rates range widely. Some research has placed the incidence as high as 74 percent, but in most populations, it appears to range between 10 and 30 percent, depending on the population studied, study setting, and study design (Rees and Addy, 2004).

A panoply of current diagnostic and treatment strategies for DH suggests considerable uncertainty among dental practitioners about how to manage this condition (Cunha-Cruz et al., 2010). The diagnosis of DH remains by exclusion of other dental and periodontal conditions that might cause pain (Holland et al., 1997), and no less than a dozen of methods are currently used for diagnosis (Cunha-Cruz et al., 2010). Most contemporary treatments seek to occlude the exposed dentin using restorative materials, laser treatment, resin-based sealants, or pharmacological agents. Among the latter group, oxalates have a particularly long history of use and acceptance by practitioners. For example, a recent survey of practicing dentists suggests that 40% use oxalates to treat DH (Cunha-Cruz et al., 2010).

Oxalates were introduced as agents to treat DH in the late 1970's to mid 1980's based on work done primarily *in vitro*. Several studies reported significant decreases in hydraulic conductance across dentin disks treated with oxalates, suggesting that oxalates limit fluid flow in exposed dentin *in vivo*, thereby reducing pain (Greenhill and Pashley, 1981; Pashley et al., 1978; Pashley et al., 1984; Pashley and Galloway, 1985). Subsequent work showed that oxalates formed precipitates within dentin tubules that blocked dentinal fluid flow (Cuenin et al., 1991). Oxalates reportedly have the added advantage of relative insolubility in acid, making them resistant to dissolution after treatment (Pereira et al., 2005).

In spite of the compelling *in vitro* work supporting the use of oxalates and relatively wide acceptance by practitioners, few controlled studies have shown their efficacy clinically, and a rigorous systematic evaluation of existing studies has not been reported. Yet, controlled data on the efficacy of oxalate treatment is essential to guide both dental practice and further research in the treatment of DH. Thus, our objective was to present a systematic review of controlled trials on humans with DH comparing an oxalate intervention to a placebo or no treatment group to reduce DH.

METHODS

Study Selection Criteria

Participants: Humans with dentin hypersensitivity. Post-restorative hypersensitivity studies were excluded.

Intervention: Oxalates

Comparison: Placebo or no treatment.

Outcomes: DH pain response to routine activities, thermal, tactile, evaporative, or electrical stimuli. Because of the heterogeneity of methods used to assess DH, no *a priori* outcome measure was required.

Studies: randomized controlled trial (RCT) or clinical controlled trial (CCT)

Search Methods to Identify Studies

After the development of a protocol, article citations were obtained through an electronic search of databases (to July 2009) and hand searching of bibliographic reference listings of published primary and review studies (for a complete list of databases, see Appendix 1). The MEDLINE and CENTRAL search strategy included the terms “dentin sensitivity”[MeSH Term] OR “dentin hypersensitivity”. Additional electronic searches were performed by two students using the terms “dentin hypersensitivity” OR “dentin sensitivity”. The Cochrane highly sensitive search strategy for identifying randomized trials (revision 2008) (Higgins and Green, 2009) was applied to restrict studies to clinical trials in MEDLINE; no language restrictions were employed. Reports identified through electronic searches of MEDLINE

and CENTRAL were coded according to participants and interventions by two independent reviewers, and agreement was calculated using the Kappa statistic.

Study Description and Risk-of-bias Assessment

Two reviewers independently performed study description and risk-of-bias assessments; disagreements were resolved by discussion among the two reviewers and a third reviewer. Where needed, authors of studies were contacted for additional information to resolve ambiguities, and their responses were accepted until April 20, 2010. Risk-of-bias was assessed using the Cochrane Collaboration tool (Higgins and Green, 2009) (for a detailed description, see Appendix 2).

Synthesis of Results

Three reviewers performed data extraction. The number of participants, means and standard deviations were extracted from the reports (for a detailed description, see Appendix 2). Based on random effect models (DerSimonian and Laird, 1986), standardized weighted-mean differences (SMD), reported in units of standard deviation, were calculated for each oxalate treatment after calculating the SMD of all outcomes for each study. For split-mouth trials, the reviewers assumed a within-patient correlation coefficient equal to 0. Heterogeneity between studies, quantified using the I^2 -statistic (Higgins and Thompson, 2002), was considered high if statistical heterogeneity levels were higher than 70%. Data were analyzed using RevMan 4.2.7.

RESULTS

Study selection

Electronic searches from all sources retrieved 677 unique citations (Fig. 1). Using titles and abstracts to screen content, 503 citations were excluded because they were not clinical studies of DH in humans, or were reviews or opinion papers. Agreement between reviewers was good (Kappa = 0.79). The remaining 174 citations were pared to 15 by evaluating full article content with information provided by correspondence with authors as needed. Four articles not previously found through electronic search were discovered in the references of citations. Of the 19 human clinical trials on oxalates, 4 did not meet the inclusion criteria and 3 were previous reports of included studies (see Appendix 3 for list of excluded trials and reasons). The remaining 12 reports (Camps and Pashley, 2003; Cooley and Sandoval, 1989; Cuenin et al., 1991; Gillam et al., 1997; Gillam et al., 2004; Hansson, 1987; Holborow, 1994; Morris et al., 1999; Muzzin and Johnson, 1989; Pamir et al., 2007; Pereira et al., 2001; Pillon et al., 2004) were subjected to detailed analysis (Table 1).

Study description

Studies included in the systematic review were diverse (Table 1), with five conducted in the United States, two each in Brazil and the United Kingdom, and one each in Turkey, France, and New Zealand. Nine of the studies were conducted in university settings, two at military installations, and one study did not report a location. Four of the studies were funded by university or government grants, three by product manufacturers, two were without external funding, and three did not report a funding source. All studies were full reports published in English between 1987 and 2007, except one that was a short communication (Holborow, 1994).

Nine of the 12 studies were split mouth trials that took various approaches to assessing oxalate efficacy (Table 1). Eight of the 12 studies evaluated some form of monohydrogen-monopotassium oxalate. Other studies included ferric oxalate, di-potassium oxalate, or oxalate-containing pre-polymerized resin; two of the studies used combinations of

monohydrogen-monopotassium and di-potassium oxalate. The placebo groups were diverse as well. Several studies used distilled water, some with dyes for blinding purposes. Two studies used the thickeners carboxymethyl cellulose or carbopol for blinding; one of these used a dye. Other studies used 4% glucose or 3% sodium chloride as placebo solutions. One study used no treatment and one did not disclose the placebo procedure. Even more diverse were the follow-up intervals, which ranged from immediate to 1 year; 4 weeks was the most common follow-up time (5 studies).

DH pain was elicited by tactile, evaporative, or thermal stimuli (11 of 12 studies), although 2 studies used reports of pain elicited by routine activities (Table 1). Eight of the 12 studies used more than one stimulator to elicit pain. DH was commonly quantified using a pain scale, with either verbal or numeric descriptors; 10 of 12 studies used at least this method to quantify DH. Other outcome measures included the force of tactile pressure or temperature of applied liquid which elicited pain. Adverse events during the studies were not observed; 1 study did not report information about adverse events and author follow-up was not successful.

Risk-of-bias assessment

Most studies reported use of random assignment of interventions. However, close scrutiny and author follow-up revealed that only 4 of the 12 studies had followed procedures to assure random sequence generation and concealed allocation strategy (Table 2). Four studies did not report sufficient information to assess these factors. Similarly, only 4 of the 12 studies took measures to assure blinding of participants, care providers, and assessors. Most studies reported blinding participants (10 of 12). The information published or provided via author communication was not sufficient to determine blinding in 2 studies.

Other factors increased the risk-of-bias. Four studies did not report point estimates, number of observations, or variability measures (Table 2). One study had a risk-of-bias via selective reporting and in another one selective reporting was unclear. One study did not specify eligibility criteria; another reported a non-equivalence of treatment and placebo groups at baseline. Of the 9 split mouth designs, five studies tried to limit cross-over effects by enrolling teeth from different areas of the mouth or isolating teeth with cotton rolls or rubber dam.

Synthesis of results

Treatment with 3% monohydrogen-monopotassium oxalate resulted in less DH as measured by thermal stimuli, tactile stimuli, and routine activities; the most favorable results were obtained when using routine activities as a measure. For other outcomes, interventions with 3% monohydrogen-monopotassium oxalate produced no change or made DH worse (for results by outcome, see Appendix 2). Data were not available for three outcomes of one study (Gillam et al., 1997), and one outcome of another study (Holborow, 1994). Based on 187 and 179 units (patients or teeth) in the intervention and placebo groups from seven studies the summary SMD for 3% monohydrogen-monopotassium oxalate was -0.71 [95% Confidence Interval (CI): $-1.48, 0.06$] with high statistical heterogeneity (88%) (Fig. 2).

A combination of 3% monohydrogen monopotassium oxalate and 30% dipotassium oxalate was the second most common intervention, and three studies evaluated its efficacy (Fig. 2). When daily activities were used as an outcome, this intervention reduced DH. However, when thermal stimuli were used, the DH was either similar or higher than the placebo group (Appendix 2). Based on 59 units in the intervention and placebo groups from three studies, the summary SMD for 30% dipotassium oxalate followed by 3% monohydrogen-

monopotassium oxalate was 0.00 (95% CI: -1.05, 1.04) with high statistical heterogeneity (92%) (Fig. 2).

Other interventions were evaluated only by single studies (Fig. 2). SMD ranged from -0.28 to +0.17, but results were not statistically significant.

DISCUSSION

This systematic review suggests no benefit from treating dentin hypersensitivity with oxalates beyond a placebo effect. Dentin hypersensitivity has an intermittent nature, and strong placebo effects have been observed which makes definitive demonstration of clinical efficacy of any treatment difficult (Pashley et al., 2008). Yet, the data suggested that 3% monohydrogen-monopotassium oxalate may have some beneficial effect; this treatment appears to be a rationale first line of oxalate treatment. Taken together, the current data cannot dissect if a lack of effect was from a truly ineffective treatment or study design limitations.

A combination of 3% monohydrogen-monopotassium oxalate and 30% dipotassium oxalate was the second-most common DH treatment assessed by clinical studies, yet its efficacy relied heavily on the outcome measure examined. This lack of significant effect was curious considering the more favorable results observed for 3% monohydrogen-monopotassium oxalate contained in the treatment regimen, and the lack of effect observed for 30% dipotassium oxalate alone. This paradox suggests some sort of interference or competition between these treatments, or important and yet unidentified factors in how the two treatments are applied. At present, there appears little motivation to use this more complex treatment regimen clinically.

The studies included in this systematic review had several design limitations. With the exception of 3% monohydrogen-monopotassium oxalate, most of the treatments were evaluated by only one study. Additionally, most studies involved small sample sizes (range 6–87 units). Further, the extent to which studies employed strict randomization, concealment, and blinding procedures varied considerably. For split-mouth trials, we considered use of isolation during product placement as a reasonable strategy to avoid cross-over effects. However, patient response to pain on different teeth is not necessarily independent, and the outcome assessment may be confounded by pain response in adjoining or distant teeth.

Lack of standardization when measuring pain and poor diagnostic criteria are difficulties facing research in the area of DH; (Markowitz and Pashley, 2008). Studies in this review used different stimuli to elicit pain and treatments decreased DH pain for some stimuli, but not others (see Appendix 2). In addition, numerical and verbal rating scales, 10-cm visual analog scales, and pain threshold tasks were used to measure pain intensity. Utility of pain scales depends on patients understanding the correct way to use the scales, and can be impacted by use of instruction sets (Dixon et al., 2004). In all, the effectiveness of DH treatments remains unclear because of diverse and sometimes lax methods that have been employed to assess efficacy to this point in time.

Taking the lack of standardized measures into account, we completed a meta-analysis using the standardized mean difference (SMD) across studies evaluating the same interventions. Whereas this method of analysis provides a clear way of assessing one overall outcome per study, the statistical heterogeneity across studies suggests that clinical and design differences among the studies were present and summary estimates may not have been presented. For instance, number of outcomes assessed, follow-up length, and criteria met on the risk of bias assessment differed among the studies. In addition, due to poor reporting of

the results in the included studies assumptions were made to extract the data. Finally, no adjustment was made for within-study correlation. How liberal or conservative the overall analysis is depends on if this correlation is negative or positive, respectively, but we could not reliably estimate or find such a correlation published in other clinical trials of DH.

In conclusion, available evidence suggests that oxalates are not effective in decreasing DH when compared to placebo; with a possible exception for 3% monohydrogen-monopotassium oxalate. These data should be considered when treating DH until further evidence is available. The great variability observed across clinical trials illuminated the need for strict study protocols including appropriate randomization and allocation concealment. Standardized use of pain stimuli and scales, both across and within studies, also would aid meta-analysis.

Acknowledgments

We would like to thank the authors of the studies included in this systematic review who answered our requests for additional information, Dr. Lei Li for translation of an article in Chinese, and Dr. D.J. Olson for helping with the electronic searches.

This work was supported by the National Institute of Dental and Craniofacial Research [grant numbers DE016750, DE016752, DE018436, and DE019202].

Appendix 2. Details on the methods of the systematic review on oxalate treatments for dentin hypersensitivity

Study Selection Criteria

Clinical controlled trials are defined as trials that definitely or possibly assigned participants to one of two (or more) alternative forms of intervention using either random allocation or some quasi-random method of allocation (such as alternation, date of birth or medical record number) (Worthington *et al.*, 2009).

Risk-of-bias

The domains of the Cochrane Collaboration tool to assess risk-of-bias (Higgins and Green, 2009) include:

1. sequence generation (identified method used to generate the random allocation sequence);
2. allocation concealment (identified method used to conceal the allocation sequence before allocation);

3. blinding of participants, care providers and outcome assessors (employed measures to blind participants and personnel from knowledge of which intervention a participant received);
4. incomplete outcome data (provided number of observations, point estimates and measures of variability for the outcome measures and adequately addressed any incomplete outcome data, e.g. by intention-to-treat or sensitivity analyses);
5. selective outcome reporting (reported study's pre-specified primary and secondary outcomes of interest); and
6. other sources of bias (e.g., extreme baseline imbalance, study stopped early, study claimed to be fraudulent, or design-specific bias). Design-specific bias was assessed for split-mouth trials and included the potential for carry-over effects.

Reviewers judged the studies for each item assigning a “Yes” or “No” if the criterion was met or not (low and high risk-of-bias) or “Unclear” if there were insufficient information to permit a judgment of ‘Yes’ or ‘No’.

Data Extraction and Analysis

Number of observations, mean and standard deviations of each outcome were extracted for the intervention and placebo groups. When the means and standard deviations were not reported, this information was solicited to the authors and/or estimated based on the reported data. Final results were preferred, but change from baseline was also included in the data analysis. Data was calculated for each study as follows:

- Pamir, 2007: data was obtained from the author.
- Gillam, 2004: standard deviations were calculated from 95% confidence intervals.
- Pillon, 2004: standard deviations for the change from baseline were calculated from the 95% confidence intervals extracted from a figure.
- Camps, 2003: standard deviations of the percentages were estimated based on an independent sample. Data for one outcome not reported or possible to estimate.
- Pereira, 2001: the numbers of observations for each treatment group at one year were estimated by assuming a 1-yr attrition rate as the same as the 6-month attrition rate published in a thesis (Martineli, 1999).
- Cooley, 1989: standard deviations for each treatment group were assumed to be equal to the standard deviation of the mean difference between treatments. The latter was calculated assuming a p-value equal to 0.01 and independent samples.
- Hansson, 1987: the different pain scales used in response to the same stimulus were combined in a single measure for that stimulus.

After obtaining the number of observations, means and standard deviations for each pain stimulus outcome, a weighted standardized mean difference (SMD) was calculated for each study summarizing the different stimuli into a single study measure. After calculating a summary SMD for each study using all outcomes from that study, an overall SMD was calculated for each oxalate treatment. For split-mouth trials, we assumed a within-patient correlation coefficient equal to 0 because this coefficient was unreported by any study, and attempts to estimate it using reported data failed to calculate a reliable estimate.

The standardized weighted-mean differences were calculated based on random effect models (DerSimonian and Laird, 1986). The SMD estimated the size of the intervention effect in each study relative to the variability observed in that study (Higgins and Green,

2009). This measure of association was selected because studies used a variety of stimuli and scales to assess DH outcomes. The summary estimate was reported in units of standard deviation. In other words, the SMD is the number of SD by which the oxalate treatment changes the outcome and can be re-expressed in the original scale of a particular instrument. As an example, let us consider the standard deviation of 2.7 for the pain elicited by the thermal stimulus and measured with a 10 cm VAS scale for the control group at baseline in one study (Pamir, 2007). A SMD of 0.7 (95%CI=-1.5, 0.06) would be equivalent to a decrease of 1.9 points on the VAS pain scale, ranging from -4 to +0.2. However, these back-transformations should be interpreted with caution because they could yield different sizes of effect for the same scale and the same effect depending on the different standard deviations used (Higgins and Green, 2009).

Appendix table presents the results by outcomes. Because of the small number of studies available for each oxalate treatment, the meta-analysis summary estimate should be interpreted with caution. In addition, influence analysis, publication bias assessment and meta-regression could not be performed.
