Abstract

The cochlear duct epithelium (CDE) constitutes a tight barrier that effectively separates the inner ear fluids, endolymph and perilymph, thereby maintaining distinct ionic and osmotic gradients that are essential for auditory function. However, *in vivo* experiments have demonstrated that the CDE allows for rapid water exchange between fluid compartments. The molecular mechanism governing water-permeation across the CDE remains elusive. We computationally determined the diffusional (P_D) and osmotic (P_f) water-permeability coefficients for the mammalian CDE based on *in silico* simulations of cochlear water dynamics integrating previously derived *in vivo* experimental data on fluid flow with expression sites of molecular water channels (aquaporins, AQPs). The P_D of the entire CDE ($P_D=8.18 \times 10^{-5} \text{ cm}\cdot\text{s}^{-1}$) and its individual partitions including Reissner's membrane (RM; $P_D=12.06 \times 10^{-5} \text{ cm}\cdot\text{s}$) and the organ of Corti (OC; $P_D=10.2 \times 10^{-5} \text{ cm}\cdot\text{s}^{-1}$) were similar to other epithelia with AQP-facilitated water permeation. The P_f of the CDE ($P_f=6.15 \times 10^{-4} \text{ cm}\cdot\text{s}^{-1}$) was also in the range of other epithelia while an exceptionally high P_f was determined for an epithelial subdomain of outer sulcus cells in the cochlear apex co-expressing AQP4 and AQP5 (OSCs; $P_f=156.90 \times 10^{-3} \text{ cm}\cdot\text{s}^{-1}$). The P_f/P_D ratios of the CDE ($P_f/P_D=7.52$) and OSCs ($P_f/P_D=242.02$) indicate an aqueous-pore-facilitated water exchange and reveal a high-transfer region or “water-shunt” in the cochlear apex. This “water-shunt” explains experimentally determined phenomena of endolymphatic longitudinal flow towards the cochlear apex. The water-

Introduction

The inner ear is a fluid-filled sensory organ enclosing two unique extracellular fluids, perilymph and endolymph. One of the most fundamental questions regarding inner ear function is how fluid regulation maintains the delicate balance of ion gradients and fluid volume between the perilymph and endolymph.

In the cochlea, the endolymph in the scala media (SM) is separated from the perilymph in the scala vestibuli (SV) by Reissner's membrane (RM) and from the perilymph in the scala tympani (ST) by the epithelium residing on the basilar membrane that includes the organ of Corti (OC) and the epithelial lining of the inner and outer sulcus (Figures 1A and 1B). Laterally, the epithelial lining of the spiral ligament (SL) including the stria vascularis closes the cochlear duct. The entire cochlear duct epithelium (CDE) is sealed by intercellular tight junctions and thereby forms the cochlear "perilymph-endolymph barrier" (PEB; [35]; Figure 1B).

The rate constants (P') for the perilymphatic-endolymphatic exchange of potassium (K^+ , $P' = 112.29 \times 10^{-6} \text{ s}^{-1}$), sodium (Na^+ , $P' = 6.37 \times 10^{-6} \text{ s}^{-1}$), chloride (Cl^- , $P' = 22.58 \times 10^{-6} \text{ s}^{-1}$), and water (H_2O , $P' = 15 \times 10^{-3} \text{ s}^{-1}$) demonstrate a high permeability for both ions and water for the entire CDE [44,42,43]. The related turnover half-time of the CDE for potassium is 55 min [44], while that for water is only ~8 min [77]. At the molecular level, several trans-membrane proteins have been identified in the CDE that specifically facilitate the transepithelial exchange of K^+ , Na^+ , and Cl^- , consistent with the high electrolyte permeability of the cochlear PEB [reviewed in 50]). Although P' for water exchange across the cochlear PEB is 130 times greater than that for K^+ , surprisingly molecular pathways that specifically facilitate water permeation across the CDE have not been elucidated. As water is known to diffuse with low permeability through lipid-bilayer membranes, the major determinant of membrane water permeability in many physiological processes is the presence or absence of molecular water channels, notably aquaporins (AQPs) [6,94,41]. The expression of eight AQP subtypes has been confirmed in the heterogeneous cell population of the CDE and its surrounding connective tissue, including AQP1–AQP7 and AQP9 [reviewed in 17]). Commonly used parameters that provide a quantitative measure of water exchange across epithelia and describe the nature of transepithelial water exchange (i.e., solubility-diffusion through the lipid bilayer membrane or aqueous pore (e.g., AQP)-facilitated water permeation) are the diffusional (P_D) and osmotic (P_f) water-permeability coefficients. P_D is a measure of the rate of water exchange across an interface (per unit area) based on thermal movements in the absence of an osmotic or hydrostatic gradient. P_f

describes overall water movement (per unit area) as a response to hydrostatic or osmotic pressure gradients. As a quantitative and comparative measure, P_D and P_f have been determined for various AQP-expressing epithelia (reviewed in [95]); however, despite the established, abundant expression of AQPs in the CDE, P_D and P_f have not been established for this epithelium, and the functional significance of AQPs in transepithelial water exchange between the cochlear perilymph and endolymph remains unknown.

In this study, we examined the hypothesis that water homeostasis in the cochlear perilymph and endolymph is maintained by AQP-based transepithelial water permeation. To this end, we determined P_D and P_f for the entire CDE and for its individual partitions, including RM, the OC, and a particular epithelial subdomain in the cochlear apex comprised of a subpopulation of outer sulcus cells (OSCs; inlay * in Figure 1B). Notably, in this subpopulation of OSCs in the rat and human cochlea, AQP4 was localised in the basolateral membrane, which stretches into the perilymphatic fluid of the spiral ligament, and AQP5 was localised in the apical membrane, which is bathed in endolymph in the SM [30]. This localisation of two AQPs in both cellular membrane domains (herein referred to as “complementary” membranous AQP expression) constitutes the molecular and cellular basis of an AQP-facilitated “water shunt” between the perilymph and endolymph across the PEB in the cochlear apex [30,18]. To date, this subpopulation of OSCs in the cochlear apex constitutes the only confirmed cell type in the CDE exhibiting a complementary membranous AQP expression.

The calculations of P_D and P_f in this study were based on previously derived *in vivo* experimental data on diffusional [43] and osmotic [77] water exchange between the perilymphatic and endolymphatic fluid compartments to respectively determine P_D and P_f for the entire CDE, its individual partitions including RM and OC as well as the epithelial subdomain in the cochlear apex comprised by the subpopulation OSCs co-expressing AQP4 and AQP5.

Furthermore, cochlear water-dynamics simulations were performed using a modified version of the *Cochlear Fluids Simulator V. 1.6i* [78]. The applicability of this computer model to the simulation of water exchange between cochlear-fluid compartments of the guinea pig cochlea was validated by comparing the *in silico* (i.e. via computer simulations)-generated data with the *in vivo* data determined on guinea pig cochleae in a study by Konishi et al. [43]. Accordingly, the diffusional water exchange was simulated to determine P_D across the entire CDE that is between the perilymph of SV and ST and the endolymph of SM (SV +ST/SM model) as well as its individual partitions which is between the SV and SM (across RM; SV/SM model) and between the ST and SM (across OC; ST/SM model).

As P_D and P_f are defined as the transport flux of water per unit membrane area [19], surface areas of the entire CDE, RM, and the OC were quantified from histological sections and previously derived morphological data of cochlear fluid space dimensions from the adult guinea pig cochlea [31]. The membrane area of complementary AQP expression in OSCs of the cochlear apex was determined by measurements of immunohistochemically labelled sections of the adult guinea pig cochlea.

We established values of P_D and P_f for the entire CDE of the guinea pig cochlea and its individual partitions (RM, OC and OSCs in the cochlear apex) that indicate aqueous-pore-facilitated water permeation. The abundant AQP expression in the CDE provides a plausible molecular basis for rapid perilymphatic-endolymphatic water exchange. For the epithelial domain of AQP4/AQP5-expressing OSCs in the cochlear apex, we determined an exceptionally high P_f that is comparable to the P_f values reported for renal-tubule epithelia. Furthermore, we present a new model of longitudinal endolymph flow that incorporates a perilymphatic-endolymphatic water exchange across a high-transfer AQP-facilitated “water shunt” in the cochlear apex. Based on this model we provide a molecular explanation for experimentally determined phenomena of endolymphatic longitudinal flow towards the cochlear apex in the dehydrated cochlea.

Materials and Methods

Animals

Adult male, pigmented guinea pigs (strain BFA bunt) weighing 700–800 g were obtained from an in-house breeding colony. The animals were maintained in an in-house animal facility with free access to food and water under standard white cyclic lighting. Three cochleae from three different animals were cryosectioned and used for double-immunolabelling of the water-channel proteins AQP4 and AQP5 ($n = 3$, Figure 5B) to determine the radial length of the apical membranes of OSCs that exhibited complementary membrane localisation of AQP4 and AQP5. The remaining three cochleae were used for whole-mount preparations of the lateral wall of the cochlear duct ($n = 3$, Figures 5C and 5D). The whole-mount preparations were double-immunolabelled for AQP4 and AQP5 to determine the longitudinal length of complementary AQP4/AQP5 localisation in OSCs. Azan-stained sections from two adult guinea pig cochleae, obtained from the histology collection of the Institute of Anatomy of the University of Tübingen, were used to measure the radial length of RM (PEB between the SV and SM) and the OC, which in this study comprises the epithelial lining on the basilar membrane reaching from the inner to the outer sulcus (PEB between the ST and SM; $n = 2$, Figures 4A and 4C).

Inner ear dissection, fixation, decalcification, embedding, sectioning, and whole-mount preparation

The animals were deeply anaesthetised by intraperitoneal injection of a mixture of fentanyl ($0.025 \text{ mg}\cdot\text{kg}^{-1}$; Albrecht GmbH, Aulendorf, Germany), midazolam ($1.0 \text{ mg}\cdot\text{kg}^{-1}$; Ratiopharm, Ulm, Germany), and medetomidine ($0.2 \text{ mg}\cdot\text{kg}^{-1}$; Albrecht GmbH) and sacrificed with an intrapulmonary injection of embutramide (0.5 ml ; T61, Intervet, Unterschleissheim, Germany). Subsequently, transcardial perfusion with a warm ($\sim 37^\circ\text{C}$) 0.9% sodium chloride solution was conducted ($\sim 100 \text{ ml}$) and followed by perfusion with warm ($\sim 37^\circ\text{C}$) 4% paraformaldehyde (PFA) (Carl Roth GmbH, Karlsruhe, Germany) in phosphate-buffered saline (PBS; $\sim 400 \text{ ml}$) until fixation-induced stiffness of the neck was confirmed. The brain was removed, and dissection of the complete bony-labyrinth capsules from the skull base was conducted in ice-cold 4% PFA in PBS. The perilymphatic spaces of each cochlea were opened by removing the stapedial footplate from the oval-window niche and removing the round-window membrane. Fixation of the inner ear was performed via a

gentle perfusion of the opened perilymphatic scalae with 4% PFA, followed by a 2-h immersion in 4% PFA. The bony capsules of the cochleae were thinned using a high-speed motorised drill prior to decalcification of the fixed specimens for 48 h in 2 mM ethylenediaminetetraacetic acid (EDTA) in PBS. For cryosectioning, the cochleae were immersed in 25% sucrose in PBS overnight and embedded in a cryo-gel (Tissue-Tec® O.C.T. compound, Sakura Finetek, Zoeterwoude, Netherlands). Midmodiolar cryosections intended for immunolabelling were cut at 14 µm lateral thickness using a cryostat (Microm, Thermo Fisher Scientific, Walldorf, Germany) and were immediately mounted on SuperFrost® Plus microscope slides (Langenbrinck, Emmendingen, Germany). For lateral wall whole-mount preparations, the otic capsule was carefully removed, and the lateral wall was then separated from the OC in the region of the Claudius cells (CCs) along the entire length of the cochlear duct and divided into 8 to 11 segments; these segments were used for immunolabelling.

Immunofluorescence labelling of Aquaporin-4 and Aquaporin-5

Based on a previous study demonstrating the complementary membranous expression of AQP4 and AQP5 in OSCs in the rat cochlea [30], AQP4 and AQP5 immunolabelling in the guinea pig cochlea was performed using a polyclonal goat anti-AQP4 antibody (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA; dilution 1:400) and a polyclonal rabbit anti-AQP5 antibody (Millipore, Billerica, MA, USA; dilution 1:100), visualised with an Alexa 594-conjugated anti-goat secondary antibody (Molecular Probes–Invitrogen, Carlsbad, CA, USA; dilution 1:400) and an Alexa 488-conjugated anti-rabbit secondary antibody, both of which had been raised in donkey (Molecular Probes–Invitrogen; dilution 1:400). All antibodies were diluted in PBS supplemented with 0.1% Triton-X 100 and 0.5% normal donkey serum (NDS). Lateral wall whole-mount preparations were stained during free-floating incubation. All cryosections and lateral wall whole-mount preparations were coverslipped using FluorSave™ mounting medium (Calbiochem–Merck, Darmstadt, Germany).

Microscopic analysis

Azan-stained sections were photographed using a Zeiss Axioplan 2 microscope (Zeiss, Göttingen, Germany). Immunolabelled cryosections and whole-mount preparations were analysed using a Zeiss 510 Meta laser-scanning microscope (Zeiss) and a Zeiss Axioplan 2 microscope (Zeiss), respectively.

Length measurements of the cochlear perilymph-endolymph barrier

The radial length (width) of RM (the membrane separating the perilymph in SV from the endolymph in SM) and the width of the OC (separating the perilymph in ST and the endolymph in SM) were determined in each of the eight cochlear half-turns (I–VIII, excluding the hook region) on midmodiolar azan-stained sections of the adult guinea pig cochlea, which were derived from two different animals (n = 2). The width of RM was determined between its two insertion points (at the spiral limbus and the spiral ligament). The width of the OC was measured along the apical cell surfaces, extending from the inner-sulcus cells (ISCs) of the spiral limbus to the OSCs of the spiral ligament. The surface of the stria vascularis that constitutes the third epithelial portion of the cochlear PEB was not

measured. We did not include the stria vascularis in our computational model because it does not provide a direct interface between the perilymphatic spaces of SV and ST and the endolymph in SM. Furthermore, water movement across the lateral wall (and the stria vascularis) does not seem to play an important role for perilymphatic-endolymphatic water exchange, as was suggested by Konishi et al. [43]. Measurements were performed using AxioVision software (V 4.8.2.0, Zeiss).

Data on the baso-apical length of the cochlear spiral of the adult guinea pig were derived from Hofman et al. [31] and used to determine the surface area of RM and the OC. In their original description, Hofman et al. [31] described the length of full cochlear turns, but not of each cochlear half-turn. Therefore, an XY projection of the cochlear spiral derived from 3D reconstruction data of the guinea pig cochlea was used to measure the individual longitudinal lengths of the eight cochlear half-turns and the hook region. Measurements were performed using the software ImageJ (V. 1.42q; National Institutes of Health, Bethesda, MD, USA).

Length measurements of complementary AQP4 and AQP5 membrane localisation in OSCs

The radial width of the apical membrane of OSCs that exhibit complementary localisation of AQP4 and AQP5 in their basolateral and apical membrane domains was determined by length measurements on immunolabelled cryosections of the adult guinea pig cochlea, which were derived from three different animals (n = 3). Corresponding longitudinal length measurements of AQP4 and AQP5 expression in the baso-apical direction were also made in OSCs from immunolabelled whole-mount preparations of the cochlear duct lateral walls derived from the remaining three cochleae of the same three animals (n = 3). The baso-apical length of AQP4 expression was determined in Claudius cells (CCs) and OSCs; the baso-apical length of AQP5 expression was measured in OSCs. The software AxioVision (V 4.8.2.0, Zeiss) was employed for the length measurements.

Data on diffusional and osmotic water exchange between the cochlear fluid compartments

Although several groups have investigated the dispersal of macromolecular marker substances, such as trypan blue [3,74], fluorescein [23,22], thorotrast [4], or peroxidase [36], between the endolymphatic and perilymphatic spaces of the inner ear *in vivo*, these techniques were not adequate to investigate permeation through the highly water-specific AQP-channels. In contrast, radioactively labelled water (tritiated water; THO) has a similar molecular structure as the water molecule (H₂O) with the exception of one hydrogen (H) that is substituted with tritium (³H). Because of this structural similarity, AQPs exhibit comparable permeability characteristics for H₂O and THO as determined on erythrocyte membranes (reviewed in [7]) that contain AQP1 [72], AQP3 [73] and AQP5 water channels [1]. Hence, in this study, we used empirical data from the study by Konishi et al. that described the diffusional exchange of THO between the perilymphatic and endolymphatic spaces in *in vivo* experiments in the adult guinea pig cochlea [43]. In their study, Konishi et al. used the following three experimental setups to determine transepithelial diffusional THO dynamics in the cochlea: (i) they measured the THO concentration in SM during THO perfusion of SV and ST to determine the rate of diffusional water flow across the entire cochlear PEB (hereafter referred to as model SV+ST/SM, Figure 2A); (ii) they measured the

THO concentration in SM during THO perfusion of SV only to determine the rate of diffusional water flow across the partition of the PEB that separates the SV and SM (hereafter referred to as model SV/SM, Figure 2B); and (iii) they measured the THO concentration in SM during THO perfusion of ST only to determine the diffusional water flow across the partition of the PEB that separates the ST and SM (hereafter referred to as model ST/SM, Figure 2C). The THO concentrations in each of the scalae were measured *in vivo* by Konishi et al. [43] 7 min after the onset of perilymphatic THO perfusion. The results of these THO measurements are given in the diagrams in Figures 2A–2C. The experimental setup in the study by Konishi et al. [43] enabled the measurement of the initial endolymphatic THO concentration changes within the first 20 min after the onset of perilymphatic THO perfusion because of the one-minute time intervals between measurements, starting at 3 min after the onset of perilymphatic THO perfusion.

The osmotic water-permeability coefficients (P_f) of the cochlear PEB were also determined based on empirical data from the literature [77]. These data were derived from *in vivo* measurements of endolymphatic volume changes during perilymphatic perfusion with a solution that was hypertonic ($400 \text{ mOsm (kg-H}_2\text{O)}^{-1}$; [77]) compared with the isotonic endolymph ($306 \text{ mOsm (kg-H}_2\text{O)}^{-1}$; [77]). Hypertonic perilymphatic perfusion generated an osmotic pressure differential between the perilymph and endolymph that led to an outflow of water from the endolymphatic fluid compartment. This outflow was quantified by measuring the relative increase in the ionic volume marker TMA^+ in the endolymphatic fluid compartment with TMA^+ -sensitive electrodes [77]. As the cochlear duct epithelium surrounding the endolymphatic fluid compartment exhibits extremely low permeability to TMA^+ , the increase in the levels of this marker in the endolymph was approximately proportional to the water lost from the endolymphatic space during hypertonic perilymphatic perfusion. According to Salt and DeMott [77], the relative TMA^+ increase in endolymph during hypertonic perilymphatic perfusion resulted from two different mechanisms: (i) reduction of the endolymph volume due to the flow of water from the endolymph into the perilymph (“Area”, endolymphatic TMA^+ +22.10%, Figures 7A and 7B) and (ii) an apically directed TMA^+ -loaded endolymph flow (“Movement”, endolymphatic TMA^+ +12.29%, Figures 3A and 3C). As the TMA^+ increase in the endolymph was caused by a proportional outflow of water from the endolymphatic compartment, we calculated osmotically induced transepithelial flows from the endolymph to perilymph (J_v) to determine P_f for the entire cochlear PEB and for OSCs that exhibit complementary membranous expression of AQP4 and AQP5.

In silico simulations of endolymphatic THO uptake during perilymphatic THO perfusion

Computer simulations of diffusional THO dispersal in the cochlear fluid compartments of SV, ST, and SM were performed using the Washington University Cochlear Fluids Simulation Program (*Cochlear Fluids Simulator*, V. 1.6i), a freely accessible program available at <http://oto2.wustl.edu/cochlea/model3.html> [78]. The program enables the simulation of the dispersal of drugs or other substances in inner ear fluid spaces based on the combination of physical processes involved in solute dispersal: diffusion, longitudinal fluid flow, and clearances to other compartments of the inner ear. Using the *Cochlear Fluids Simulator* software, the diffusion coefficient of THO ($2.3 \times 10^{-9} \text{ m}^2 \cdot \text{s}^{-1}$) for the cochlear

PEB was calculated based on the formula weight (22.03 mol^{-1}). Other parameters used to configure the program were adapted from Konishi et al. [43] and are given in Table 3.

For the simulation of THO dispersal in the SV+ST/SM model (Figure 2A), a modified version of the *Cochlear Fluids Simulator* (V. 1.6i) was used. This model allowed simultaneous perfusion of both perilymphatic scalae according to the experimental setup from Konishi et al. [43]. To simulate diffusional THO exchange between one of the perilymphatic scalae (SV or ST) and the SM (models SV/SM and ST/SM; Figures 2B and 2C), we defined an unphysiologically high value for the time constant “half-time of intercompartmental substance exchange between the SV and ST” in the *Cochlear Fluids Simulator* (“scala-scala communications”, Table 3) to avoid THO exchange between the SV and ST. The half-times of substance exchange between the SV and SM and between the ST and SM were adjusted by fitting the curve of endolymphatic THO concentration change to the endolymphatic THO concentration measured *in vivo* after 7 min of perilymphatic perfusion (Figures 6A–6C, data points *; Figures 6A–6C, SM in the diagrams). THO dispersal in the SV+ST/SM, SV/SM, and ST/SM models was simulated for 10 min (Figures 6A–6C) and for 120 min (Figures 6D–6F) of perilymphatic perfusion to show the initial slope and the steady-state plateau of the endolymphatic THO concentration, respectively. The curves of the simulated endolymphatic THO concentration change from Figures 6D–6F were used for regression analyses to determine the rate constants of perilymphatic-endolymphatic THO (water) exchange (P'_w) for the three models (Figures 6G–6I).

Results

Water permeability coefficients for the entire CDE, RM and OC were determined in this study based on previously derived *in vivo* experimental data on the diffusive [43] and osmotic water exchange [77] across these epithelial boundaries in the guinea pig cochlea. Konishi et al. [43] measured the diffusive uptake of radioactively labeled water (tritiated water, THO) into the endolymph during simultaneous (SV and ST) and separate perfusion of the perilymphatic scalae (SV or ST) with THO. During simultaneous THO-perfusion of SV and ST (for further details see methods section; SV+ST/SM model, Figure 2A) diffusive uptake of THO into the endolymph occurred across the entire CDE; during separate THO-perfusion of SV (SV/SM model, Figure 2B) or ST (ST/SM model, Figure 2C) endolymphatic THO uptake occurred only across RM or OC, respectively. This data was used in the present study to determine P_D values for the entire CDE (SV+ST/SM model), RM (SV/SM model) and OC (ST/SM model).

Salt and DeMott [77] measured the concentration changes of the ionic volume marker (tetramethylammonium, TMA^+) in the endolymphatic compartment during perilymphatic perfusion with media that were hyper- or hypoosmolar compared to the endolymph. During hyperosmolar perilymphatic perfusion the osmotically driven outflow of water from the endolymphatic compartment was indirectly measured by the concentration increase of TMA^+ (for further details see methods section; Figure 3A). This osmotically driven water outflow from the endolymphatic compartment induced two phenomena; (i) shrinkage of the entire endolymphatic compartment (Figure 3B; presumably via transepithelial water outflow along the entire CDE) and (ii) longitudinal endolymph flow towards the cochlear apex

(Figure 3C; via an unknown mechanism). These data were used in the present study to determine P_f values for the entire CDE (SV+ST/SM model) and a subpopulation of OSCs in the cochlear apex (OSC_{apex}), respectively.

Surface areas of the cochlear perilymph-endolymph barrier

The water-permeated surface areas of the cochlear PEB in the models 1.) SV+ST/SM, 2.) SV/SM, and 3.) ST/SM were determined. The radial width of RM, separating SV and SM (black dotted line, Figure 4A (inlay ‡)); direct permeation barrier in the SV/SM model), and that of the OC, separating ST and SM (black dashed line, Figure 4A (inlay ‡)); direct permeation barrier in the ST/SM model) were measured in each of the eight cochlear half-turns (Figure 4A, I–VIII). Additionally, we measured the length of the 8.5 cochlear half-turns (including the hook region) on a XY projection of the cochlear spiral that was derived from 3D reconstruction data of the guinea pig inner ear (Figure 4B, adapted from [31]; reprinted with the kind permission from the corresponding author R. Hofman and the publisher *Wiley-Blackwell*). The results of the width and length measurements determined in Figures 4A and 4B are shown in Figure 4C.

The surface areas of RM and the OC were calculated using equation (1) for each of the 8.5 cochlear half-turns (A_{I-VIII}) as follows:

$$A_i = l_i \times \frac{w_i + w_{i+1}}{2}, \quad i = h, I, II, III, IV, V, VI, VII, VIII \quad (1)$$

where h, I, II, III, IV, V, VI, VII, VIII are the indices for the hook-region (h) and the cochlear half-turns I – VIII, l_i is the baso-apical, longitudinal length of the i -th cochlear half-turn ($l_h - l_{VIII}$, 2B and 2C) and w_i and w_{i+1} are the widths of RM or the OC at the basal (w_i) and apical end (w_{i+1}) of the corresponding half-turn (Figure 4C). For the hook region, the width of RM and the width of the OC measured in the first cochlear half-turn (w_1), multiplied by the length of the hook region (l_h), was used. The calculated partial surface areas for RM ($A_{SV/SM, i}$) and the OC ($A_{ST/SM, i}$) from each cochlear half-turn and the hook region were summed to obtain the total surface sub-areas of $A_{SV/SM}$ and $A_{ST/SM}$ of the cochlear PEB ($A_{SV/SM} + A_{ST/SM}$).

The results from these measurements were as follows:

$A_{SV/SM} = 11.46 \text{ mm}^2$ of the cochlear PEB separating the SV from SM (RM);

$A_{ST/SM} = 9.78 \text{ mm}^2$ of the cochlear PEB separates the ST from the SM (OC) and from this it follows that 21.24 mm^2 separates the SV and ST from the SM ($A_{SV+ST/SM}$).

Membrane area of complementary membranous aquaporin expression in OSCs at the perilymph-endolymph barrier

Midmodiolar cryosections revealed that OSCs in cochlear half-turns I–V were covered by CCs at their apical pole and thus did not have direct contact with the endolymphatic space (Figure 5A, I–V). In contrast, OSCs in the three most apical half-turns were interposed between CCs and spiral-prominence (SP) epithelial cells; thus, the apical membranes of OSCs in half-turns VI–VIII had direct contact with the endolymph (Figure 5A, VI–VIII).

Immunolabelling of AQP4 and AQP5 on midmodiolar cryosections of the adult guinea pig cochlea revealed polarised membranous expression of AQP4 and AQP5 in OSCs in the cochlear apex (OSC_{apex}). AQP4 labelling was present in the basolateral membranes (covering the root processes) of OSCs in cochlear half-turns VII and VIII (Figure 5B, VII and VIII); AQP5 labelling was detected in the apical membranes and the subapical cytoplasm of OSCs and was restricted to the most apical half-turn (Figure 5B, VIII).

The radial width of the apical membranes of OSCs that exhibited AQP5 expression as determined on immunolabelled cryosections was $57.53 \pm 2.92 \mu\text{m}$ (Figure 5B, VIII, white dotted line; Table 1; $n = 3$).

The longitudinal extent of complementary AQP4 and AQP5 expression in OSCs along the baso-apical length of the cochlear duct was determined from whole-mount preparations of the lateral wall from the adult guinea pig cochlea (Figures 5C and 5D). Consistent with the results obtained from immunolabelled cryosections (Figure 5B), AQP4 labelling in CCs was observed throughout the entire length of the cochlear duct (Figure 5D, I–VIII). AQP4 labelling in OSCs was detected along the entire longitudinal length of the lateral wall of half-turn VIII ($818.61 \pm 16.53 \mu\text{m}$, (Figure 5D, VII; Table 1; $n = 3$) and further extended along $930.34 \pm 24.70 \mu\text{m}$ in half-turn VII. Overlapping fluorescence signals for AQP4 and AQP5 were restricted to a distance of $804.31 \pm 73.28 \mu\text{m}$ in the most apical half-turn (Figure 5D, VIII; Table 1; $n = 3$).

The total length of the cochlear half-turns (Figure 5D) was derived from length measurements of the adult guinea pig cochlear spiral (Figures 4B and 4C; [31]). The measurements on three whole-mount preparations of the lateral wall obtained from three different animals revealed a between-subject variation of the longitudinal extent of AQP4 and AQP5 labelling in OSCs of 2.02% and 9.10% (measured values, see Table 1), respectively. These values are higher than the range of inter-individual variation determined for the length of the basilar membrane of the guinea pig cochlea described as 0.83% [84]. This variance can be due to technical variations in the segmental whole-mount preparation of the lateral wall or a greater inter-individual variation in the longitudinal extent of AQP4 and AQP5 in the cochlear lateral wall.

The value of the radial width of the apical membranes of OSCs that exhibit complementary expression of AQP4 and AQP5 ($57.53 \pm 2.92 \mu\text{m}$; Table 1; $n = 3$) was multiplied by the longitudinal membrane length of complementary expression of AQP4 and AQP5 in OSCs ($804.31 \pm 73.28 \mu\text{m}$), yielding an OSC area (A_{OSC}) of $46,271.95 \mu\text{m}^2$ (0.04627 mm^2). This area represents a putative aquaporin-facilitated water shunt at the perilymph-endolymph barrier in the apex of the cochlea.

Rate constants of diffusional water exchange at the cochlear perilymph-endolymph barrier

Konishi et al. [43] determined P' for the entire cochlear PEB based on experimental *in vivo* data describing time-dependent endolymphatic uptake of THO during simultaneous THO perfusion of both perilymphatic scalae (SV+ST/SM model, Figure 2A). In this model, Konishi et al. recorded the endolymphatic THO concentration in one-minute intervals, starting three minutes after the initiation of perilymphatic THO perfusion. The data points of

the time-dependent endolymphatic THO concentration changes in the SV+ST/SM model were used by Konishi et al. for regression analysis based on equation (2):

$$C_e^* = C_0^* \left[\frac{P'}{P''} + \frac{\alpha P' - 0.5 P' P''}{P''(P'' - \alpha)} e^{-P' t} - \frac{0.5 P'}{P'' - \alpha} e^{-\alpha t} \right]. \quad (2)$$

In equation (2), C_e^* is the THO concentration in the endolymph, C_0^* is the final concentration of THO in the perilymph, P' is the rate constant of THO exchange between the perilymph and endolymph, P'' is the rate constant of THO outflow from the endolymphatic compartment, and α is the time constant determining the slope of the change in the endolymphatic THO concentration. The least-squares fit to equation (2) by Konishi et al. [43] yielded $P' = 0.85 \text{ min}^{-1}$ for the SV+ST/SM model. For the SV/SM and ST/SM models, no continuous measurements of endolymphatic THO concentration changes were performed by Konishi et al.; thus, P' was not determined for the SV/SM and ST/SM models.

In this study, we determined P' for the entire cochlear PEB via *in silico* simulations with the *Cochlear Fluids Simulator* (V 1.6i, modified). The endolymphatic THO uptake derived from the SV+ST/SM model (Figure 6G) was calculated as 0.869 min^{-1} (Table 2). This *in silico* value is consistent with the empirical *in vivo* value of 0.85 min^{-1} measured by Konishi et al. [43]. Hence, cochlear water dynamics simulations performed *in silico* also enabled calculations of P' for the models in which perilymphatic scalae were separately perfused with THO. The data points of endolymphatic THO concentration measured *in vivo* 7 min after the onset of perilymphatic perfusion [43] were used in the *in silico* simulations for curve fitting. Based on the simulations performed in this study, P' was calculated as 0.691 min^{-1} for the SV/SM model (Figure 6H; Table 2) and 0.499 min^{-1} for the ST/SM model (Figure 6I; Table 2). The *in silico* determined P' values for the SV+ST/SM, SV/SM, and ST/SM models were further used for P_D calculations.

Diffusional water permeability coefficients of the cochlear perilymph-endolymph barrier

Calculations of P_D were based on surface quantifications of the cochlear PEB and *in silico* simulations of diffusional THO dispersal between the perilymphatic and endolymphatic scalae performed with the *Cochlear Fluids Simulator* (V 1.6i, modified). In our P_D calculations for the cochlear PEB, we made the following assumptions: (i) transepithelial THO permeation occurred only across RM in the SV/SM model, across the OC in the ST/SM model, and across both epithelial structures in the SV+ST/SM model; and (ii) the continuous perilymphatic perfusion minimized unstirred layer effects, which therefore did not contribute significantly to the resistance of water diffusion across the plasma membranes of the cochlear duct epithelium; and (iii) the pre-existing osmotic gradient between the endolymph ($304.2 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$; [43]) and perilymph ($293.5 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$ in the SV and $292.9 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$ in the ST; [43]) diminished with the onset of perilymphatic perfusion. Consistent with this assumption, Konishi et al. confirmed the absence of significant differences in osmolarity between the SM, SV, and ST after perilymphatic perfusion by measuring the osmolarities in the cochlear scalae. Therefore, THO dispersal between the perilymphatic and endolymphatic spaces was driven only by the diffusional spread of the tracer and not by solvent drag.

P_D values for the cochlear PEB were calculated using equation (3), which was derived from [43]:

$$P_D = \frac{P' V_e}{A} \quad (3)$$

where P' is the rate constant of transepithelial diffusional water exchange between perilymph and endolymph, derived from our *in silico* simulations of the SV/SM, ST/SM, and SV+ST/SM models. V_e is the endolymph volume (1.2 μl in the adult guinea pig cochlea; [90]), and A is the water-permeated surface area of the PEB, which was determined in this study for the SV/SM ($A_{SV/SM}$), ST/SM ($A_{ST/SM}$), and SV+ST/SM ($A_{SV+ST/SM}$) models. For RM, we found the following: $P' = 0.691 \text{ min}^{-1}$, and $A_{SV/SM} = 11.46 \text{ mm}^2$. Substitution of these values into equation (3) yielded a value for P_D of $12.06 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$ for RM (SV/SM model). For the OC (ST/SM model) with $P' = 0.499 \text{ min}^{-1}$ and $A_{ST/SM} = 9.78 \text{ mm}^2$, we calculated $P_D = 10.2 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$. For the entire cochlear PEB (SV+ST/SM model) with $P' = 0.869 \text{ min}^{-1}$ and $A_{SV+ST/SM} = 21.24 \text{ mm}^2$, we calculated $P_D = 8.18 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$ (Figure 7).

Osmotic water permeability coefficients of the cochlear perilymph-endolymph barrier

P_f calculations for the cochlear PEB were based on data on surface areas of the cochlear PEB, data on the membrane area of complementary AQP4/AQP5 expression in OSCs, and *in vivo* experimental data on osmotically induced changes in endolymphatic volume (Material and Methods, Figure 2). For the P_f calculations performed in this study, the following assumptions were made: (i) the decrease in the area of the SM during hypertonic perfusion of SV and ST [77] was caused by an osmotically induced transepithelial volume flow from the endolymphatic to the perilymphatic space; (ii) this transepithelial outflow of endolymph occurred throughout the entire baso-apical length of the cochlear duct, across RM and the OC; (iii) the continuous perilymphatic perfusion minimized unstirred layer effects, which therefore did not contribute significantly to the resistance of water permeation across the plasma membranes of the cochlear duct epithelium; (iv) the apically directed endolymph flow in the SM [77] was caused by an osmotically induced transepithelial bulk-volume flow from the endolymph to the perilymph across a water shunt consisting of AQP4/AQP5-expressing OSCs in the apex of the cochlear duct; (v) the experimentally determined increase in endolymphatic TMA⁺ induced by shrinkage of the endolymphatic compartment (area) and apically directed endolymph flow (movement) was considered to be approximately linear within 20 min of hypertonic perilymphatic perfusion (Materials and Methods, Fig 10); and (vi) after 20 min of hypertonic perilymphatic perfusion, the osmotic gradient between the perilymphatic and endolymphatic spaces remained constant. Consequently, an approximately linear increase in endolymphatic TMA⁺ resulted from the linear volume outflow.

The transepithelial volume flows (J_v) per second ($\text{cm}^3 \text{ s}^{-1}$), which induced shrinkage of the endolymphatic compartment (area, $J_{v\text{-area}}$) and apically directed endolymph flow (movement, $J_{v\text{-movement}}$), were calculated using equation (4):

$$J_v = \left(V_e \cdot \frac{SI}{100\%} \right) / 20 \quad (4)$$

where V_e is the endolymph volume in the adult guinea pig cochlea (1.2 μl ; [90]) and SI is the relative solute (TMA^+) increase induced by shrinkage of the endolymphatic compartment ($SI_{\text{Area}} = 22.1\%$) and longitudinal volume flow ($SI_{\text{Movement}} = 12.29\%$), as measured 20 min after the onset of hypertonic perilymphatic perfusion [77].

With $V_e = 1.2 \mu\text{l}$ and $SI_{\text{Area}} = 22.1\%$, $J_{v\text{-Area}}$ equals $13.26 \times 10^{-3} \mu\text{l}\cdot\text{min}^{-1}$; with $V_e = 1.2 \mu\text{l}$ and $SI_{\text{Movement}} = 12.29\%$, $J_{v\text{-Movement}}$ is $7.37 \times 10^{-3} \mu\text{l}\cdot\text{min}^{-1}$.

Calculations of P_f for the cochlear PEB were based on equation (5):

$$P_f = \frac{J_v}{\bar{V}_w \cdot A \cdot \Delta c} \quad (5)$$

which is derived from [19], where J_v is the transepithelial net volume flow, \bar{V}_w is the partial molar volume of water ($18 \text{ cm}^3\cdot\text{mol}^{-1}$), A is the water-permeated surface area of the PEB, and Δc is the osmotic gradient between perilymph and endolymph. Because Salt, DeMott [77] perfused the perilymphatic compartments of the SV and ST with a solution that was made hypertonic ($400 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$) compared with the endolymph in the SM ($306 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$) by the addition of 94 mM sucrose (Materials and Methods, Figure 3), Δc between the endolymph and perilymph was $0.094 \text{ mol}\cdot\text{l}^{-1}$. P_f for the entire cochlear PEB, based on the variables $A_{\text{SV+ST/SM}}$ (21.24 mm^2) and $J_{v\text{-Area}}$ ($13.26 \times 10^{-3} \mu\text{l}\cdot\text{min}^{-1}$) and on equation (6), equals $6.15 \times 10^{-4} \text{ cm}\cdot\text{s}^{-1}$. The P_f for OSCs that exhibit complementary membranous expression of AQP4 and AQP5 (OSC_{apex}) was determined based on the values of A_{OSC} (0.04627 mm^2) and $J_{v\text{-Movement}}$ ($7.37 \times 10^{-3} \mu\text{l}\cdot\text{min}^{-1}$) and on equation (6) and equals $156.90 \times 10^{-3} \text{ cm}\cdot\text{s}^{-1}$ (Figure 7).

Estimation of the membrane density of AQP5 water channels in the apical membranes of OSCs

The density of AQP5 water channel proteins in OSCs (n_{AQP5}) was estimated based on the single channel water permeability for AQP5 ($P_{f\text{-AQP5}} \sim 5 \times 10^{-14} \text{ cm}^3\cdot\text{s}^{-1}$ [98]) and the transepithelial P_f of OSC_{apex} ($156.90 \times 10^{-3} \text{ cm}\cdot\text{s}^{-1}$) from this study. n_{AQP5} for OSC_{apex} was determined using equation (6) which was derived from Dobbs et al. [15]

$$n_{\text{AQP5}} = \frac{P_{f\text{-OSC}}}{P_{f\text{-AQP5}}} \quad (6)$$

with $3.45 \times 10^4 \mu\text{m}^{-2}$.

Discussion

This study assessed the diffusional (P_D) and osmotic (P_f) water-permeability coefficients of the CDE in the guinea pig model. Based on these results, four lines of evidence (i–iv) reveal

the physiological relevance of AQP-mediated perilymphatic-endolymphatic water exchange in the mammalian cochlea:

(i) Quantitative comparison of P_D and P_f for the entire cochlear duct epithelium yields water-permeability coefficients in the same range seen in epithelia with aquaporin-facilitated water permeation

A comparison of P_D ($8.18 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$) and P_f ($6.15 \times 10^{-4} \text{ cm} \cdot \text{s}^{-1}$) for the entire CDE with water-permeability coefficients reported for various other AQP-expressing epithelia revealed that these values were of the same order of magnitude while non AQP-expressing cells demonstrate much lower values (Figure 8). The P_D and P_f values that most closely resemble those of the CDE are those reported for the conjunctival epithelium of the ocular bulb ($P_D = 13 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$, [11]; $P_f = 11 \times 10^{-4} \text{ cm} \cdot \text{s}^{-1}$, [53]; Figure 8). Notably, both the CDE and the conjunctival epithelium are classified as “tight” barriers [43,10,32,35]. Water flow across these tight epithelia thereby occurs via a transmembranous route and is most likely facilitated by AQPs that are expressed in the epithelial membrane domains (apical and basolateral) that face the two separated extracellular fluid compartments at the ocular surface (tear film and extracellular fluid in the conjunctival stroma) and in the cochlea (endolymph and perilymph), respectively. In the conjunctival epithelium (and in the corneal epithelium that is continuous with the conjunctival epithelium), AQP3 [70,27,53] in the baso-lateral domain [38] and AQP5 [66] at the apical ocular surface domain [38] determine the primary route of transepithelial water permeation as indicated by a four- and five-fold reduction in membrane osmotic water permeability (P_f) in transgenic mice lacking AQP3 or AQP5 water channels, respectively [53].

In the CDE a complementary membranous localisation of AQPs (AQP4 and AQP5) has only been established for the OSCs in the outer sulcus region of the cochlear apex [present study,30,29,18]. However, for many other cell types in the CDE the expression of multiple AQP-subtypes has been described (reviewed in [17]), e.g. AQP7 and AQP9 in the epithelium of RM that separates the endolymph in the SM and perilymph in the SV, and AQP2, AQP4, AQP5, AQP7, and AQP9 in supporting cells of the OC that divides the endolymph in the SM and perilymph in the ST. Although a complementary localisation of AQPs in the basolateral and apical membranes of these cells has not been established it appears likely that further analysis will obtain additional complementary expression patterns at the subcellular level. The presence of multiple AQPs in most of the cells types in the tight CDE and the similarity of P_D and P_f values suggest transmembranous AQP-facilitated water permeation across the entire CDE, as has been experimentally demonstrated for multiple AQP-expressing epithelia (Figure 8).

In summary, the presence of several AQP-subtypes in various cells of the CDE and the similarity between P_D and P_f values of the entire CDE and multiple other AQP-expressing epithelia strongly suggest a transmembranous AQP-facilitated water permeation across the entire CDE.

(ii) The ratios of P_f/P_D determined for the cochlear duct epithelium and aquaporin-expressing outer sulcus cells account for an aqueous-pore-mediated water permeation

The ratio of osmotic-to-diffusional water permeability (P_f/P_D) exceeds unity ($P_f/P_D > 1$) in the case of an aqueous pore (e.g., AQP)-facilitated water permeation [19]. In this study, the ratio P_f/P_D for the entire CDE was determined to be 7.52 (Figure 8), a value that clearly exceeds 1. In contrast, epithelia that do not exhibit AQP-facilitated water permeation, such as Madin-Darby canine kidney (MDCK) type I monolayers ([51]; Figure 8) or pure phospholipid-bilayer membranes ([13]; Figure 8), exhibit a P_f/P_D ratio that equals unity ($P_f/P_D \sim 1$). At these interfaces, water permeation occurs by solubility-diffusion through the lipid bilayers rather than through aqueous pores [19]. All other epithelia listed in Figure 6 express multiple AQPs in a complementary membranous distribution. Consistent with AQP-facilitated transepithelial water permeation, these epithelia exhibit P_f/P_D ratios > 1 , with values ranging from 2.03 for the (non-ADH-stimulated) kidney cortical collecting duct ([48]; Figure 8) to 1307.69 for the lung alveolar epithelium ([20]; Figure 8). The P_f/P_D ratio, determined for the entire CDE (7.52) closely resembles the value of the conjunctival epithelium ($P_f/P_D = 8.46$; Figure 8) or the submandibular salivary gland epithelium ($P_f/P_D = 6.67$; Figure 8). Notably, in both of these epithelia, AQP5 water channels are localised in the apical cell membranes [58,24,53] and determine the rate-limiting barrier for transepithelial water permeation (in case of the salivary gland acinar cells under pilocarpine-stimulated saliva secretion [57,47,53]).

To determine the ratio P_f/P_D for the subdomain of AQP5-expressing OSCs in the cochlear apex ($P_f/P_D = 242.02$, Figure 8), we assumed a P_D for these cells ($P_{D-OSC_s} = 64.83 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$), which represents a mean of the experimentally determined P_D values of AQP5-expressing epithelia, i.e. the lung alveolar epithelium ($1.30 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$, [12]), the corneal epithelium ($1.68 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$, [21]), the cochlear duct epithelium ($8.18 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$, present study), the conjunctival epithelium ($13 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$, [11]) and the salivary gland acinar epithelium ($300 \times 10^{-5} \text{ cm} \cdot \text{s}^{-1}$, [89]). This value closely resembles the P_f/P_D ratios determined for the renal proximal tubule epithelium, as well as the proximal and distal colon epithelium (Figure 8) in which the transepithelial fluid reabsorption largely depends on AQP-facilitated water permeation.

In summary, the ratios P_f/P_D determined for the entire CDE ($P_f/P_D = 7.52$) and the AQP4/AQP5-expressing subpopulation of OSCs in the cochlear apex ($P_f/P_D = 242.02$) clearly exceed 1, and therefore indicate aqueous-pore-facilitated transepithelial water permeation between the perilymph and endolymph. A comparison of both values reveals that the different cell types of the CDE apparently do not uniformly contribute to transepithelial water permeation. The exceedingly high ratio determined for AQP-expressing OSCs indicates a high-transfer region for transepithelial water permeation in the cochlear apex.

(iii) The absolute P_f values determined for the entire CDE and the epithelial subdomain of OSCs in the cochlear apex reveal a highly permeable AQP4/AQP5-based water shunt in the cochlear apex

An absolute value of P_f greater than $1 \times 10^{-2} \text{ cm} \cdot \text{s}^{-1}$ indicates aqueous pore-facilitated water permeation [93]. For the entire CDE, we determined a considerably lower P_f of 6.15×10^{-4}

$\text{cm}\cdot\text{s}^{-1}$; however, the cochlear duct is a highly heterogeneous epithelium that consists of 12 morphologically and functionally diverse cell types. Many of these cell types exhibit distinct AQP expression patterns, while others are devoid of AQP expression (reviewed in [17]). Hence, the cellular constituents of the CDE apparently exhibit distinct water permeability characteristics and the P_D and P_f values calculated in this study for the entire CDE, RM, and the OC therefore represent average values of the diffusional and osmotic water permeabilities in the CDE.

In this study, we determined the P_f of a single cell type of the CDE, a subpopulation of AQP4/AQP5-expressing OSCs in the cochlear apex, to be $156.90\times 10^{-3} \text{ cm}\cdot\text{s}^{-1}$ (Figure 7). This exceptionally high P_f value is 280-fold higher than the average P_f of the entire CDE ($6.15\times 10^{-4} \text{ cm}\cdot\text{s}^{-1}$; Figure 7) and clearly exceeds the value of $1\times 10^{-2} \text{ cm}\cdot\text{s}^{-1}$, which indicates aqueous pore-facilitated water permeation across OSCs. In accordance with the results from previous light microscopic [83] and ultrastructural [16] studies, we found this subpopulation of OSCs in the most apical half-turns (VI–VIII) of the guinea pig cochlea to be exclusively interposed between CCs and SP epithelial cells, thereby representing direct constituents of the cochlear PEB. Moreover, in this study, the complementary membranous localisation of AQP4 (basolateral) and AQP5 (apical) was demonstrated in this particular subpopulation of OSCs of the cochlear apex. The complementary subcellular distribution of AQP4 and AQP5 in this specific subpopulation of apically located OSCs has previously been described in rat [30] and human [30,18] cochleae. As AQPs in the membranes of this subpopulation of OSCs putatively mediate transmembranous water exchange between the endolymph and OSC cytoplasm (AQP5), as well as between the OSC cytoplasm and the perilymphatic extracellular fluid of the spiral ligament (AQP4), they form the molecular basis for an AQP-facilitated “water shunt” between the endolymph and perilymph, as previously proposed [30,17].

Quantitatively, the P_f of OSCs is comparable to the P_f of the kidney proximal-convoluted-tubule (PCT) epithelium ($500\times 10^{-3} \text{ cm}\cdot\text{s}^{-1}$, Figure 8; [9]). In the PCT epithelium, AQP1 in the apical and basolateral membranes [63], and AQP7 in the apical membranes [33] represent the major constituents of membrane osmotic water permeability [80,85] and thereby facilitate the reabsorption of 50–60% of the fluid filtered by the glomeruli (i.e., ~98 litres per day), in order to maintain whole-body water homeostasis. The P_f value of OSCs in the cochlear apex, which matches that of the PCT epithelium, suggests a high water transport capacity for OSCs that are potentially relevant for cochlear water homeostasis.

In summary, the P_f values determined for the entire CDE and the epithelial subdomain of AQP4/AQP5-expressing OSCs in the cochlear apex differ by two orders of magnitude. This suggests highly heterogeneous water permeability characteristics among the different cell types in the CDE. For OSCs in the cochlear apex, which are a direct constituent of the PEB, we propose a high capacity AQP-“water shunt” that enables passive bulk water movements between the endolymph and perilymph contributing to longitudinal flow.

(iv) The estimated AQP5 channel density in the apical membranes of OSCs substantiates a high-transfer “water shunt” in the cochlear apex

The density of AQP5 channel proteins in the apical membranes of OSCs in the cochlear apex was estimated to be $3.45 \times 10^4 \mu\text{m}^{-2}$. This value represents the characteristic AQP membrane density of 10^3 – $10^4 \mu\text{m}^{-2}$ as found in many cell membranes [92], and is in particular close to the membrane density of AQP5 channels determined in the alveolar epithelium ($1.4 \times 10^4 \mu\text{m}^{-2}$; [15]). Notably, these characteristic AQP membrane densities exceed that of ion channels ($1 \mu\text{m}^{-2}$) by several orders of magnitude.

Water flow across the “water shunt” in OSCs of the cochlear apex is presumably rate-limited by AQP5 in the apical membrane, since (i) the basolateral membrane that enwraps the root processes of OSCs forms a larger membrane area for water permeation, and (ii) the single channel water permeability of AQP4 ($P_{f\text{-AQP4}} \sim 25 \times 10^{-14} \text{ cm}^3 \cdot \text{s}^{-1}$; [98]) in the basolateral membranes of OSCs is 5-times higher than that of AQP5 ($P_{f\text{-AQP5}} \sim 5 \times 10^{-14} \text{ cm}^3 \cdot \text{s}^{-1}$ [98]).

In summary, the estimated membranous AQP5 channel density in OSCs provides a plausible molecular basis for the high osmotic water permeability determined for this epithelial subdomain in the CDE.

Putative physiological significance of the aquaporin-facilitated water shunt in outer sulcus cells in longitudinal endolymph homeostasis

A putative driving force for transcellular water movement across the AQP-water shunt in OSCs of the cochlear apex is the osmotic gradient of $11 \text{ mOsm (kg} \cdot \text{H}_2\text{O)}^{-1}$ between the perilymph ($293 \text{ mOsm (kg} \cdot \text{H}_2\text{O)}^{-1}$; [43]) and endolymph ($304 \text{ mOsm (kg} \cdot \text{H}_2\text{O)}^{-1}$; [43]), as measured in the guinea pig cochlea under physiological conditions. This osmotic gradient is primarily determined by the ionic composition of the inner ear fluids and by the permeability of the cochlear PEB to ions [44,42,43,10]. Alterations in the ion content in inner ear fluids, e.g., by the systemic administration of glycerol [37] or by disturbance of the ionic permeability of the PEB (e.g., induced broadband noise [45], low-frequency-sound stimulation [75], or hypothermia [46]) affect the perilymphatic-endolymphatic osmotic gradient and thus affect the driving force for transepithelial water movement between the fluid compartments. The prevailing osmotic gradient therefore shifts and drives passive transepithelial water flows into or out of the endolymphatic fluid compartment. Experimental studies *in vivo* have shown that the volume of cochlear endolymph was reduced by perfusing the perilymphatic spaces with hypertonic medium and at the same time induced an apically directed endolymph flow of $2.5 \text{ nl} \cdot \text{min}^{-1}$ ([77]; Figure 9B). Similarly, when the osmotic gradient between the perilymph and endolymph was reversed, a slower basally directed endolymph flow was observed ([77]; Figure 9C). This basally directed endolymph flow was also induced by acute volume injections into the cochlear endolymph [76]. Notably, even under the physiological conditions with an osmotic gradient between perilymph and endolymph ($11 \text{ mOsm (kg} \cdot \text{H}_2\text{O)}^{-1}$; [43]), the mean rate of endolymph flow directed toward the base was calculated to be $0.36 \text{ nl} \cdot \text{min}^{-1}$; this value has been classified as not significantly different from zero and therefore indicates the absence of longitudinal endolymph flow under normal conditions [79]. These *in vivo* experimental findings were in

line with the long-standing “dynamic flow theory” for endolymph, which was introduced by Lawrence et al. [52]. This theory attempts to explain the fundamental mechanisms of endolymph generation and homeostasis by combining the concepts of local “radial flow” of endolymph [61] as the predominant homeostatic mechanism under physiological conditions (indicated by the absence of longitudinal flow [79]) and the “longitudinal flow” [25] as a compensatory homeostatic mechanism that occurs exclusively in disturbed endolymphatic fluid (indicated by longitudinal flow when endolymph volume [76] or perilymphatic-endolymphatic gradients are altered [77]); however, experimental evidence for these proposed mechanisms of endolymph homeostasis is sparse. The longitudinal endolymph flow *in vivo* was extremely low in the normal animal [79] but could be induced by experimental manipulations [77,76]. Conversely, the radial endolymph flow has never been demonstrated experimentally. Large radial currents have been demonstrated [100] and it is widely accepted that major ions, such as K^+ , are recycled [87]; however, volume flows associated with local ionic circulation are thought to be minimal and hence endolymph is not secreted in volume. Moreover, no molecular determinants in the cells of the cochlear duct epithelium have been described that account for endolymph volume movements.

Here, we propose that bidirectional longitudinal endolymph movements generated under conditions of an endolymph volume disturbance (as demonstrated experimentally *in vivo* [77]) are induced by osmotic bulk water flow out of (apically directed endolymph flow, Figure 9B) and into (basally directed endolymph flow, Figure 9C) the endolymphatic fluid compartment through the AQP-facilitated water shunt in the cochlear apex at the helicotrema (Figure 10A and 10B). The AQP-facilitated water shunt thereby enables OSCs in the cochlear apex to function to secrete and resorb endolymph as postulated in previous studies using this cell type [83,2, reviewed in 34]; these results support the contribution of longitudinal flow to endolymph homeostasis in the cochlea.

Putative pathophysiological significance of the aquaporin-facilitated water shunt in outer sulcus cells in disturbed inner-ear-fluid homeostasis (e.g., Ménière’s disease)

The disturbance of longitudinal endolymph flow is regarded as an essential component of the formation of EH. As idiopathic EH is an obligatory histopathological finding in Ménière’s disease [97,26], the disturbance of longitudinal endolymph flow has been considered a critical component of the aetiology of this inner ear affliction. In attempts to identify the underlying cause of Ménière’s disease, the results of numerous morphological and functional studies pointed to the ES as the main site causing the disturbance of endolymphatic-volume homeostasis [62,40,25,55]; however, a failure in active secretion and/or resorption of the endolymph by the ES fails to conclusively explain morphological and functional alterations localised in the cochlear apex of Ménière’s disease animal models and temporal bone specimens derived from Ménière’s disease patients. For example in *post mortem* human temporal bone specimens, EH in the apical turn of the cochlea is the first histopathomorphologic sign and was observed in each of the 95 cases investigated in a study by Pender [71]. Later during disease progression, EH becomes most severe in the cochlear apex and further extends to other portions of the membranous labyrinth [67,71]. Furthermore, degenerative changes in sensory and neural elements, as well as functional impairment (i.e., low-frequency hearing loss), primarily manifest in the cochlear apex.

These pathological abnormalities were attributed to chronic alterations in the local fluid environment of the cochlear apex [81]. Ménière's disease-specific abnormalities in the cochlear apex that explain these morphological and functional impairments have not yet been described at the molecular level.

Recently, molecular-epidemiologic studies investigating the association of AQP5 gene polymorphisms with susceptibility to Ménière's disease [5,65] identified a single-nucleotide polymorphism (SNP) in the AQP5 gene (rs3736309) that was associated with a reduced risk of Ménière's disease [65]. In other studies, carriers of the same SNP were shown to have a reduced risk of chronic obstructive pulmonary disease (COPD) [64,28]. Serious symptoms of COPD are mucus hypersecretion and lung oedema, indicating the pathophysiological significance of airway submucosal gland epithelia (secreting most of the airway mucus) and the distal lung epithelium (reabsorbing the alveolar fluid) in COPD. In both airway epithelia, AQP5 expressed in the apical membranes determines the rate-limiting barrier for transepithelial fluid transport [86,56]. These findings suggest a protective effect of the AQP5 SNP against lung-fluid imbalances caused by AQP5-dependent transepithelial water permeation in COPD. Analogously, in the cochlea, the AQP5 SNP most likely alters the water permeability of the AQP4/AQP5 water shunt in OSCs of the cochlear apex and may therefore prevent EH formation and hence reduce the risk for Ménière's disease. These epidemiologic studies, in conjunction with the molecular and *in silico* functional characterisation of the AQP4/AQP5 water shunt in OSCs in this study, imply that it has a role in the pathophysiology of EH formation and Ménière's disease. Furthermore, pharmacological interventions aimed at the AQP4/AQP5 water shunt in the cochlear apex may form a basis for future medical therapies in Ménière's disease.

In conclusion, we showed that in the mammalian cochlea the diffusive (P_D) and osmotic (P_f) water permeability coefficients of the entire cochlear duct epithelium indicate aqueous-pore mediated transepithelial water permeation between the endolymph and perilymph. We further identified a high-transfer region for osmotic water flow between the endolymph and perilymph in the cochlear apex, constituted by an epithelial subdomain of outer sulcus cells that express the water channel proteins AQP4 and AQP5 in their basolateral and apical membranes, respectively. Bulk water flow across this AQP-water shunt putatively drives osmotically induced longitudinal endolymph flows and may be of pathophysiological significance in the generation of endolymphatic hydrops in Ménière's disease.

Acknowledgments

We thank Priv.-Doz. Dr. Bernhard Hirt from the Institute of Anatomy of the University of Tübingen for providing the azan-stained histological sections of the guinea pig cochleae from the "Heidenheim"-collection. We gratefully acknowledge the continued support and critical reading of the manuscript by Dr. Ernst Dalhoff and Dr. Erich Goll. We thank Dr. Karina Gültig for excellent technical assistance. The author AE was supported by the Institutional Strategy of the University of Tübingen (Deutsche Forschungsgemeinschaft, ZUK 63). The author ANS was supported by NIH/NIDCD grant DC001368.

Abbreviations

A_{OSC}	membrane area of OSCs that co-express AQP4 in their apical membranes and AQP5 in their basolateral membranes (μm^2)
A_{ST/SM}	water-permeated surface area of supporting cells of the organ of Corti (μm^2)
A_{SV/SM}	water-permeated surface area of Reissner's membrane (μm^2)
A_{SV+ST/SM}	water-permeated surface area of the entire cochlear duct (μm^2)
AQP	aquaporin
α	time constant
CCs	Claudian cells
Cl⁻	chloride
C₀[*]	final concentration of THO (tritiated water) in the perilymph ($\text{mol}\cdot\text{l}^{-1}$)
C_e[*]	THO (tritiated water) concentration in endolymph
c	osmotic gradient between perilymph and endolymph ($\text{mol}\cdot\text{l}^{-1}$)
DAPI	4',6-diamidino-2-phenylindole
EDTA	ethylene-diamine-tetra-acetic acid
EH	endolymphatic hydrops
ES	endolymphatic sac
H₂O	water
J_v - Area	transepithelial volume outflow from endolymph that induced shrinkage of the endolymphatic compartment ($\text{cm}^3\cdot\text{s}^{-1}$)
J_v - Movement	transepithelial volume outflow from endolymph that induced longitudinal endolymph flow ($\text{cm}^3\cdot\text{s}^{-1}$)
K⁺	potassium
mOsm	milliosmole
Na⁺	sodium
NDS	normal donkey serum
OSCs	outer sulcus cells
P_D	diffusional water permeability coefficient ($\text{m}\cdot\text{s}^{-1}$)
P_f	osmotic water permeability coefficient
P'	rate constant of perilymphatic-endolymphatic THO exchange (min^{-1} ; according to [4]) P'', rate constant of endolymphatic water extrusion (min^{-1} , according to [4])
PBS	phosphate-buffered saline

PEB	perilymph-endolymph barrier
PFA	paraformaldehyde
SI_{Area}	endolymphatic solute (TMA ⁺) increase induced by shrinkage of the endolymphatic compartment (according to [5])
SI_{Movement}	endolymphatic solute (TMA ⁺) increase induced by longitudinal endolymph flow (according to [5])
SM	scala media
SP	spiral prominence
ST	scala tympani
ST/SM	experimental model with THO perfusion of ST to determine P' for OC
SV	scala vestibuli
SV/SM	experimental model with THO perfusion of SV to determine P' for RM
SV+ST/SM	experimental model with THO perfusion of SV and ST to determine P' for the entire CDE
t	time (min)
THO	tritiated water
TMA⁺	tetramethylammonium
V_e	endolymph volume (μl)
V_w	partial molar volume of water (18 cm ³ ·mol ⁻¹)

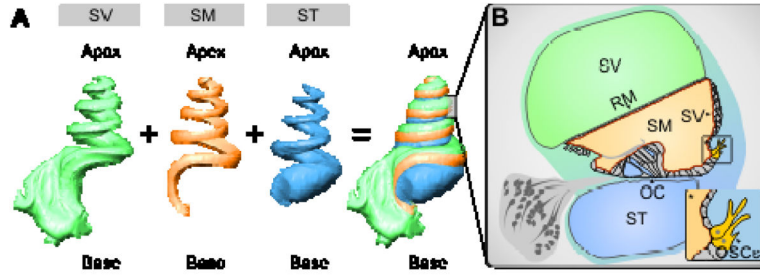

Figure 1.

Three-dimensional (3D) reconstruction of orthogonal-plane fluorescence optical sectioning (OPFOS) data from the guinea pig cochlea to demonstrate the anatomical relations of the cochlear fluid spaces. (A) 3D reconstruction of the endolymphatic space in the scala media (SM) and the perilymphatic spaces in the scala tympani (ST) and scala vestibuli (SV). (B) Schematic cross-sectional view of the guinea pig cochlear duct in the half-turn V. The cochlear duct epithelium (orange) and interepithelial tight-junctions constitute the cochlear “perilymph-endolymph barrier (PEB, red line) that encloses the endolymph in the SM. Two partitions of the cochlear PEB, namely Reissner’s membrane (RM) and the organ of Corti (OC), directly separate the endolymph in the SM from the perilymph in the SV and ST. The stria vascularis (SV) does not form a direct epithelial barrier between the cochlear fluid compartments of SV, SM and ST. In the inlay *, the position of the outer sulcus cells (OSCs) in the cochlear duct epithelium is illustrated.

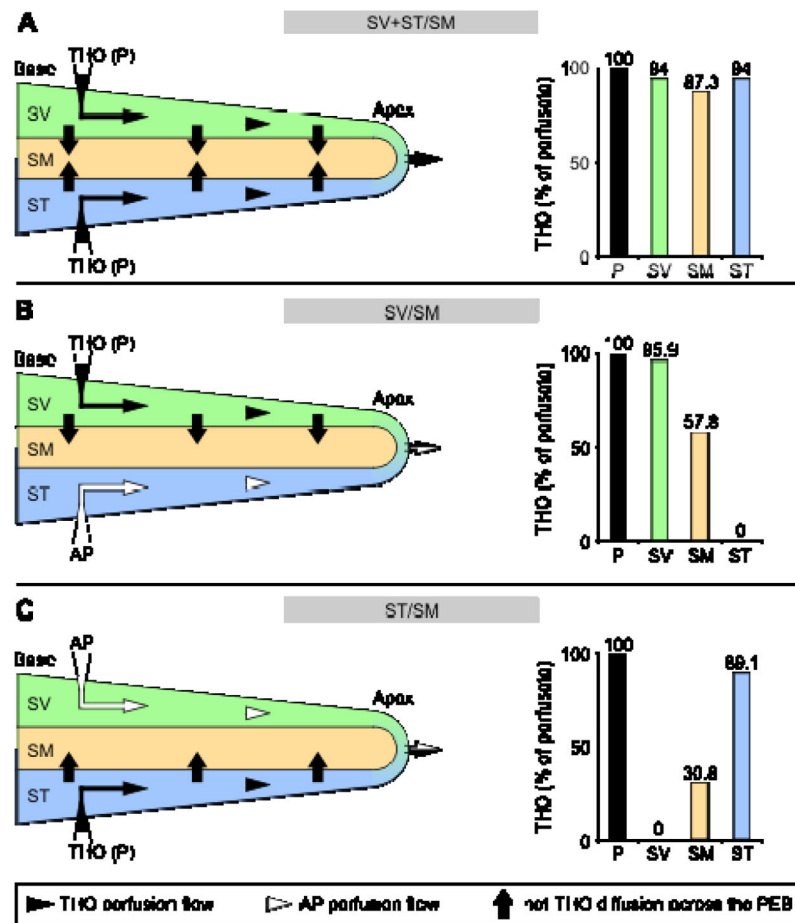

Figure 2.

Experimental models for the determination of diffusional perilymphatic-endolymphatic water exchange in the *in vivo* experimental study by Konishi et al. [43]. (A) In the SV +ST/SM model, both perilymphatic scalae, namely the scala vestibuli (SV) and the scala tympani (ST), of the adult guinea pig cochlea were perfused with a fluid (P) containing tritiated water (THO). A cochleostomy in the helicotrema region served as an outlet for the perfusion fluids. Transepithelial THO diffusion into the endolymphatic fluid compartment of the scala media (SM) occurred across the cochlear perilymph-endolymph barrier (PEB) between the SV and SM, as well as between the ST and SM. THO concentrations in the SV, ST, and SM were measured 7 min after the initiation of perilymphatic perfusion (the diagram shows the relative THO concentrations in the perfusion fluid (100%) and the cochlear scalae; more intense shades of grey in the diagrams indicate higher THO concentrations). (B) In the SV/SM model, the SV was perfused with THO, while artificial perilymph (AP) was injected into the ST. THO diffused from the SV to the SM across the portion of the cochlear PEB that is interposed between these two fluid compartments (i.e., Reissner's membrane). (C) In the ST/SM model, the ST was perfused with THO and the SV was rinsed with AP. THO diffused from the ST to the SM across the portion of the cochlear PEB that separates the ST and SM (i.e., the epithelial boundary on the basilar membrane). Adapted from [43] with permission from the publisher, *Elsevier*.)

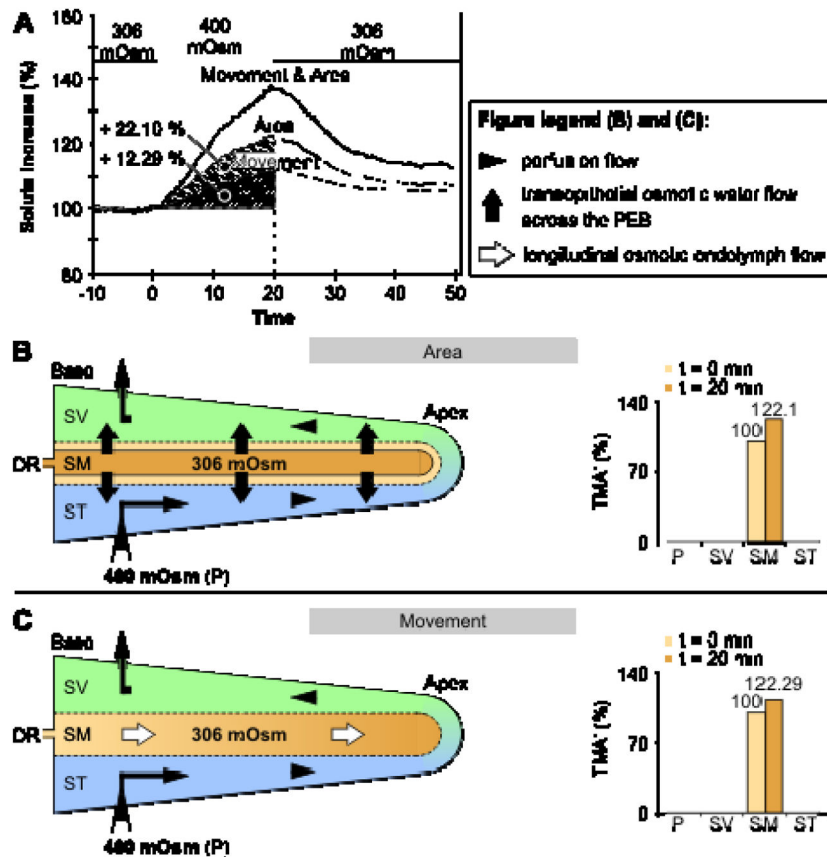

Figure 3. Mechanisms of endolymphatic volume marker increase during perilymphatic perfusion with hypertonic media in the *in vivo* experimental study of Salt, DeMott [77]. Hypertonic ($400 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$) perfusion of the perilymphatic scalae (scala vestibuli, SV; scala tympani, ST) in the adult guinea pig cochlea induced osmotic volume changes of the endolymph in the scala media (SM). These volume changes were quantified by Salt, DeMott [77] by measuring the concentration change of the ionic volume marker tetramethylammonium (TMA^+) after its iontophoretic injection into the endolymph prior to hypertonic perilymphatic perfusion. Salt and DeMott identified two different mechanisms that accounted for the increase in endolymphatic TMA^+ , i.e., shrinkage of the endolymphatic compartment ((A) and (B), area; TMA^+ increased by 22.1%) and apically directed longitudinal flow of TMA^+ -loaded endolymph ((A) and (B), movement; TMA^+ increased by 12.29%). As the epithelial boundary of the cochlear duct is nearly impermeable to TMA^+ , the induced endolymphatic TMA^+ increase can be attributed to a loss of endolymph volume that was proportional to the measured TMA^+ increase. DR, ductus reunions; adapted from [77] with permission from the publisher, *Elsevier*.

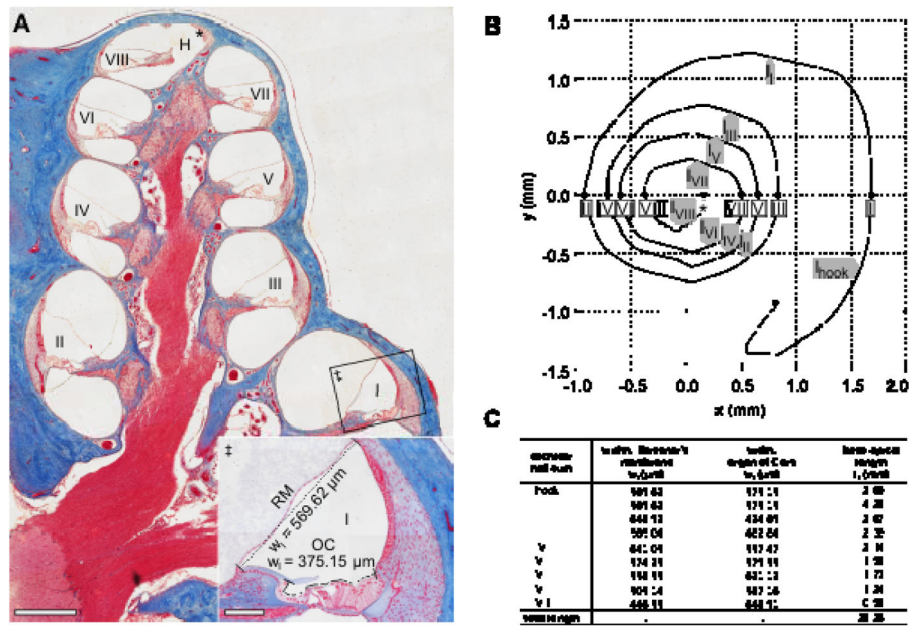

Figure 4.

Determination of surface areas of the cochlear perilymph-endolymph barrier (PEB) on the adult guinea pig cochlea. **(A)** Overview of an azan-stained lateral (midmodiolar) section of the adult guinea pig cochlea. The width (radial length) of Reissner's membrane (RM) separating the SV from the SM (\ddagger , dotted line) and the width of the apical surface of the organ of Corti (OC) separating the ST from the SM (\ddagger , dashed line) were measured in all eight cochlear half-turns (W_I - W_{VIII}) (H, helicotrema; *, apical end of the cochlear duct). **(B)** The baso-apical (longitudinal) length of RM and that of the OC were determined for each cochlear half-turn based on orthogonal plane fluorescence optical sectioning (OPFOS) data of the adult guinea pig cochlea, derived from Hofman et al. [31]. An OPFOS-based projection of the cochlear spiral in the XY plane ((B), adapted from Hofman et al. [31] with permission from the corresponding author and the publisher, *Wiley-Blackwell*) was used to measure the longitudinal length of the eight cochlear half-turns (l_I - l_{VIII}) and the hook region (l_h). **(C)** Results of width and length measurements determined in (A) and (B). Scale bars: (A) 500 μm ; (A, \ddagger) 100 μm .

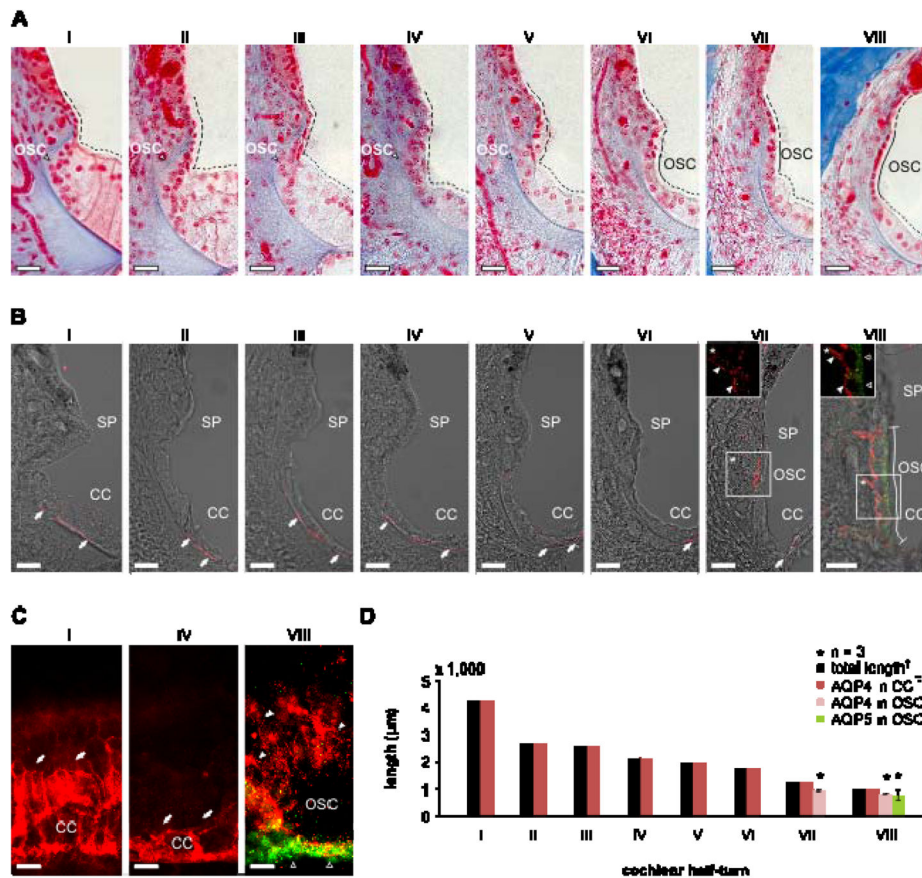

Figure 5. Complementary localisation of AQP4 and AQP5 in the apical and basolateral membranes of outer sulcus cells (OSCs) in the adult guinea pig cochlea. **(A)** The outer sulcus region in all eight cochlear half-turns (I–VIII) from azan-stained sections of the adult guinea pig cochlea. In cochlear half-turns I–V, the epithelial lining of the endolymphatic space in the outer sulcus region is formed by Claudius cells (CCs, black dotted lines mark the apical surface of CCs) and epithelial cells of the spiral prominence (SP, black broken lines mark the apical surface of SP epithelial cells). In these basal half-turns, OSCs are covered by CCs and the SP epithelial cells and therefore have no direct contact with endolymph. In contrast, in half-turns VI–VIII, OSCs are interposed between CCs and SP epithelial cells and thus are a direct constituent of the PEB. **(B)** Confocal images of immunofluorescence labelling of AQP4 (red) and AQP5 (green) in the outer sulcus region of the adult guinea pig cochlea. In half-turns I–VI, AQP4 labelling was detected in the basal membranes of CCs (white arrows). No immunoreactivity for AQP4 and AQP5 was detected in the OSCs of these half-turns. In half-turn VII, AQP4 labelling was observed in the basal membranes of CCs (white arrow), and OSCs showed AQP4 labelling in their basolateral membranes that enwrap their root processes (*, white arrowheads) but were devoid of AQP5 labelling. In the most apical half-turn (VIII), OSCs exhibited AQP4 labelling in their basolateral membranes (inlay *, white arrowheads) and AQP5 labelling in their apical membranes (inlay *, hollow arrowheads). The radial length of the apical membranes of OSCs in half-turn VIII that exhibited immunolabelling for AQP4 and AQP5 was measured as $56.19 \pm 2.47 \mu\text{m}$ (VIII,

white dotted line; $n = 3$). (C) Representative images of AQP4 (red) and AQP5 (green) immunolabelling on whole-mount preparations of the lateral wall in the half-turns I, IV and VIII that were used for baso-apical length measurements of AQP4 and AQP5 expression in OSCs. In the half-turns I and IV, AQP4 labelling was detected in CCs (white arrows). In the half-turn VIII, OSCs exhibited a polarised labelling of AQP4 (white arrowheads) and AQP5 (hollow arrowheads) in the basolateral root processes and at the apical side of the cells, respectively: (D) Quantification of the baso-apical length of AQP4 and AQP5 labelling in the outer sulcus region on whole-mount preparations of the cochlear lateral wall from each of the eight half-turns (I–VIII). AQP4 labelling in CCs was observed throughout the entire length of the whole-mount preparations. In OSCs, AQP4 labelling was restricted to a baso-apical length of $928.64 \pm 34.68 \mu\text{m}$ ($n = 3$) in half-turn VII and $827.04 \pm 10.95 \mu\text{m}$ ($n = 3$) in half-turn VIII. Additionally, in half-turn VIII, AQP5 labelling was detected in OSCs that also exhibited AQP4 labelling in their root processes along a baso-apical length of $749.86 \pm 173.76 \mu\text{m}$ ($n = 3$). (†, the length of the entire cochlear lateral wall was derived from [31]; ‡, the baso-apical length of AQP4 labelling in CCs was set equal to the total length of the lateral wall because we did not observe a baso-apical gradient of AQP4 labelling in CCs). Scale bars: (A and B) $20 \mu\text{m}$, (C) $10 \mu\text{m}$.

Figure 6. Simulations of time-dependent diffusional THO dispersal in the cochlear fluid compartments during perilymphatic tracer perfusion using the *Cochlear Fluids Simulator* (V. 1.6i). The program settings used for the simulations were adapted from the three experimental models SV+ST/SM, SV/SM, and ST/SM ([43]; Figure 2) and are provided in Table 3. (A–C) Simulations of the time-dependent THO dispersal in the perilymphatic and endolymphatic scalae during 10 min of perilymphatic THO perfusion in the SV and ST ((A), SV/SM), SV ((B), SV/SM), and ST ((C), ST/SM). Data points of endolymphatic THO concentration after 7 min (*) were obtained from *in vivo* experiments [43] and were used to fit the curve of endolymphatic THO concentration change by adjusting the parameter “scala-scala communication” (Table 3). (D–F) Simulation settings from (A–C) were applied to simulate the steady-state conditions of THO dispersal during 100 min of perilymphatic perfusion in the models SV+ST/SM (D), SV/SM (E), and ST/SM (F). (G–I) Curves of endolymphatic THO concentrations from D–I (black lines) were used for regression analyses based on equation (2). The obtained regression curves that best fit the simulation data are shown as red square lines. In (G), the *in vivo* measured data points of endolymphatic THO concentration (grey squares) and the corresponding regression line (grey line) derived from Konishi et al. [43] are shown. A comparison of the regression curve that was based on our *in silico* simulations (red square line) with the regression line derived

from empirical data (grey line) revealed an almost identical slope and a similar plateau under steady-state conditions of both curves.

Figure 7.

Results for calculated diffusional (P_D) and osmotic water permeability coefficients (P_f) of Reissner's membrane (RM; PEB between the SV and SM), the organ of Corti (OC; PEB between the ST and SM), the entire cochlear duct epithelium (CDE; entire cochlear PEB), and the apically located OSCs, which exhibited complementary membranous localisation of AQP4 in the basolateral membrane and AQP5 in the apical membrane. Y-axis on the logarithmic scale.

Figure 8.

(A) Comparison of transepithelial diffusional (P_D) and osmotic water-permeability (P_f) coefficients of AQP-expressing endo-/epithelia, including the values of the entire cochlear duct epithelium and the AQP4/5-expressing outer sulcus cells in the cochlear apex that were determined in this study. The P_f/P_D ratios were calculated in this study. Y-axis on the logarithmic scale; references are given in the figures.

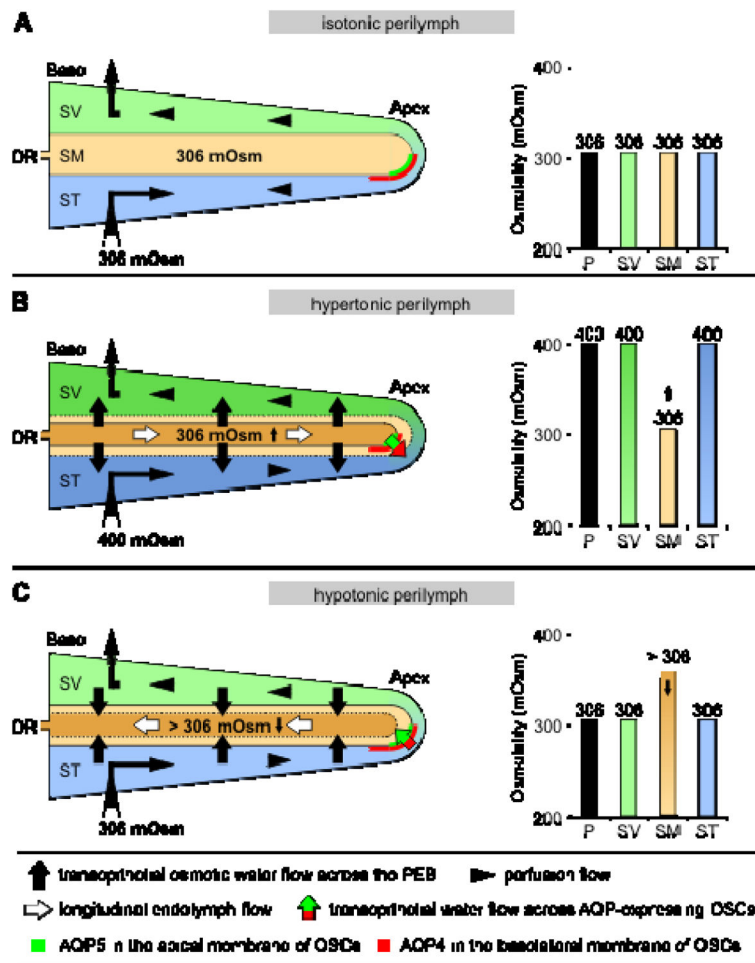

Figure 9.

Hypothetical mechanisms of osmotically induced, AQP4- and AQP5-dependent transepithelial water flow in the cochlear apex and the effect of this flow on longitudinal endolymph flow. (A) In the *in vivo* experiments by Salt, DeMott [77], perfusion of the scala tympani (ST) and the scala vestibuli (SV) with a solution that was iso-osmotic to the endolymph (306 mOsm (kg·H₂O)⁻¹) had no effect on endolymph volume or longitudinal endolymph flow in the scala media (SM). (B) Hyperosmotic (400 mOsm (kg·H₂O)⁻¹) perilymphatic perfusion induced shrinkage of the endolymphatic compartment, presumably via osmotically induced transepithelial water outflow along the entire cochlear duct epithelium. Moreover, the longitudinal endolymph flow was into the blind-ending apex of the cochlear duct. This longitudinal flow can be explained by a bulk outflow of water from endolymph across the PEB in the cochlear apex, facilitated by AQP5 in the apical membranes and AQP4 in the basolateral membranes of OSCs in direct contact with the endolymph. (C) When the perilymphatic perfusion solution was changed back to 306 mOsm (kg·H₂O)⁻¹, a partial recovery of endolymph volume was measured by Salt, DeMott [77]. This endolymphatic volume increase was potentially induced by transepithelial water inflow along the entire cochlear duct epithelium in response to a reversed perilymphatic-endolymphatic gradient (volume outflow in (C) led to an increase in the levels of

endolymphatic osmolytes ($> 306 \text{ mOsm (kg}\cdot\text{H}_2\text{O)}^{-1}$). Consequently, the observed basally directed longitudinal endolymph flow during rehydration of the endolymphatic space [77] may be based on the osmotically induced transepithelial bulk inflow of endolymph through AQP4 and AQP5 in the membranes of OSCs in the apex of the cochlear duct epithelium (DR, ductus reuniens).

Figure 10.

Anatomical localisation of the AQP-water shunt in OSCs, illustrated in an orthogonal-plane fluorescence optical sectioning (OPFOS)-based three-dimensional reconstruction of the helicotrema region in the adult guinea pig cochlea. The AQP-water shunt (red outline) communicates along a distance of $804.31 \pm 73.28 \mu\text{m}$ with the endolymph in the scala media (SM; green outline) and with the perilymph at the confluence of the scala vestibuli (SV; light blue outline) and the scala tympani (ST; dark blue outline) in the helicotrema. Scale bar: $500 \mu\text{m}$.

Table 1

Results from baso-apical length measurements of AQP4 and AQP5 and AQP 5 radial width immunofluorescence in OSCs in the half-turns VII and VIII of the adult guinea pig cochlea.

	baso-apical length of AQP4-IF (μm)	baso-apical length of AQP5-IF (μm)	radial width of AQP5-IF (μm)
<i>half-turn VII</i>			
Specimen 1	904.12	-	-
Specimen 2	953.16	-	-
Specimen 3	933.74	-	-
Mean value	930.34	-	-
SD	24.70	-	-
<i>half-turn VIII</i>			
Specimen 1	834.78	726.99	60.23
Specimen 2	819.30	872.73	57.93
Specimen 3	801.75	813.22	54.44
Mean value	818.61	804.31	57.53
SD	16.53	73.28	2.92

Measurements were taken on three specimens (1–3) derived from three independent animals. IF, immunofluorescence; SD, standard deviation.

Table 2

Results of nonlinear regression analyses for the simulated time-dependent endolymphatic THO concentration change in the experimental models SV/SM, ST/SM, and SV+ST/SM.

	SV/SM	ST/SM	SV+ST/SM	in vivo SV+ST/SM (Konishi et al., 1984)
P' (min^{-1})	0.691	0.499	0.869	0.85
P'' (min^{-1})	0.938	0.940	0.898	0.9
α (min^{-1})	0.504	0.435	0.549	0.4

The variables P' (rate constant of THO exchange between the perilymph and endolymph), P'' (rate constant of endolymphatic water extrusion), and α (time constant) are given in equation (2).

Table 3

In vivo experimental parameters in the study by Konishi et al. [43] and their adaption in the present study for *in silico* simulations using the *Cochlear Fluids Simulator* (V 3.080).

	Konishi et al. (1984)	Cochlear Fluids Simulator (V 1.6i, modified)
species	guinea pig	guinea pig
tracer substance (TS)	THO	THO (MW: 22.0315)
TS – diff.-coeff.		$2.3004 \times 10^{-5} \text{ cm}^2 \cdot \text{s}^{-1}$
TS – conc. in perfusate	$2 \mu\text{Ci ml}^{-1}$ (normalised to 100%)	100%
TS – perfusion rate	$8 \mu\text{l} \cdot \text{min}^{-1}$	$8 \mu\text{l} \cdot \text{min}^{-1}$
TS – perfusion period	3 – 20 min	0 – 120 min
TS – entry site	basal turn	basal turn (0.1 mm from base)
TS – exit site	helicotrema	apical end of SV (15.5 mm from base) and ST (16.2 mm from base)
TS – method of conc. measurements	endolymph sampling	continuous measurements
location of measurement	SM (basal turn)	SM, SV, ST (1 mm from base)
scala-scala communications*	–	SV-SM = 2.2 min ST-SV = 9999 min ST-SM = 4.6 min
scala-blood communications*	–	SV-blood = 1.6 min ST-blood = 1.6 min SM-blood = 15 min

Software settings and parameters that are not explicitly mentioned were applied in the standard configuration.

*, software parameters defined on the basis of experimental data from [43].
