Coagonist release modulates NMDA receptor subtype contributions at synaptic inputs to retinal ganglion cells

Keywords

NMDA receptor; AMPA receptor; Glycine; Retinal Ganglion Cell; Retinal Bipolar Cell; synaptic transmission; Retina

NMDA receptors (NMDARs) are tetrameric protein complexes usually comprising two NR1 and two NR2 subunits. Different combinations of four potential NR2 subunits (NR2A-D) confer diversity in developmental expression, subsynaptic localization, and functional characteristics, including affinity for neurotransmitter. NR2B-containing NMDARs, for example, exhibit relatively high affinity both for glutamate and the coagonist glycine. Although multiple NMDAR subtypes can co-localize at individual synapses, particular subtypes often mediate inputs from distinct functional pathways. In retinal ganglion cells (RGCs), NMDARs contribute to synaptic responses elicited by light stimulus onset (“ON”) and offset (“OFF”), but roles for particular NMDAR subtypes – and potential segregation between the ON and OFF pathways – have not been explored. Moreover, elements in the retinal circuitry release two different NMDAR coagonists, glycine and D-serine, but the effects of endogenous coagonist release on the relative contribution of different NMDAR subtypes are unclear. Here, we show that coagonist release within the retina modulates the relative contribution of different NMDARs in the ON pathway of the rat retina. By pharmacologically stimulating functional pathways independently in acute slices and recording synaptic responses in RGCs, we show that ON inputs, but not OFF inputs, are mediated in part by NMDARs exhibiting NR2B-like pharmacology. Furthermore, suppressing release of NMDAR coagonist reduces NMDAR activation at ON synapses and increases the relative contribution of these putative NR2B-containing receptors. These results demonstrate direct evidence for evoked coagonist release onto NMDARs and indicate that modulating coagonist release may regulate the relative activation of different NMDAR subtypes in the ON pathway.

Activation of NMDARs requires coincident binding of glutamate and a coagonist, which can be either glycine (Johnson and Ascher, 1987) or D-serine (Mothet et al., 2000). Although the coagonist binds the two NR1 subunits in the NMDAR tetramer (Lynch et al., 1994), the identity of the NR2 subunits (NR2A-D) determines affinity for both the coagonist and glutamate (Dingledine et al., 1999). NMDARs expressing different NR2 subunits can co-localize within a synapse (Tovar and Westbrook, 1999); because NMDARs may not be saturated by synaptic levels of glutamate (Mainen et al., 1999; Ishikawa et al., 2000; McAllister and Stevens, 2000) or coagonist (Vyklícky et al., 1990; Wilcox et al., 1996; Panatier et al., 2006), higher-affinity subtypes within a mixed population may be activated preferentially during synaptic

transmission. Accordingly, mechanisms that regulate available concentrations of transmitter could change the relative contributions of NMDAR subtypes to synaptic signaling.

In the retina, NMDARs on ganglion cells (RGCs) are activated by glutamate released from cone bipolar cells (CBCs) in spatially segregated ON and OFF pathways (Mittman et al., 1990; Sagdullaev et al., 2006). All four NR2 subunits are expressed in vertebrate retina (Brandstatter et al., 1994; Watanabe et al., 1994; Grunder et al., 2000), and both NR2A and NR2B are prevalent in the inner plexiform layer (IPL; Fletcher et al., 2000), where NMDARs are localized on RGC dendrites (Grunert et al., 2002), but it remains unknown how different NMDAR subtypes contribute to RGC synaptic responses. ON and OFF inputs could express distinct NMDAR subtypes, similar to other neurons receiving input from multiple pathways (Kawakami et al., 2003; Kumar and Huguenard, 2003; Arrigoni and Greene, 2004). Alternatively, NMDARs at these inputs might have differential access to glutamate (Sagdullaev et al., 2006) or the coagonist (Lukasiewicz and Roeder, 1995), the identity (glycine versus D-serine) of which remains uncertain. Several types of amacrine cells provide inhibitory glycinergic input to RGCs (Kolb, 1979; Menger et al., 1998), but whether this glycine reaches spatially segregated excitatory synapses, and whether ambient glycine levels saturate NMDARs, is unclear. D-serine, present in Müller glia (Stevens et al., 2003), also may contribute to NMDAR activation in the retina (Gustafson et al., 2007).

To investigate how coagonist levels and NMDAR subunit composition interact to regulate NMDAR activation on RGCs, we recorded EPSCs from RGCs in acute slices of rat retina. We find that a significant fraction of synaptically activated NMDARs in the ON pathway, but not the OFF pathway, are sensitive to an NR2B NMDAR-selective antagonist. Within the ON pathway, the relative contribution of NR2B-containing NMDARs to the EPSC is modulated by coagonist release, and synaptic stimulation can increase coagonist levels from subsaturating to saturating concentrations. Together, these results demonstrate an important role for coagonist release in regulating the synaptic activation of different NMDAR subtypes on RGCs.

Materials and Methods

Slice preparation and solutions

Acute retinal slices were prepared from Sprague-Dawley rats and transgenic mice (17–23 d) in accordance with the guidelines of the National Institute of Neurological Disorders and Stroke Animal Care and Use Committee, as described previously (Chen and Diamond, 2002). Following anesthesia and decapitation, both eyes were removed and immersed in oxygenated extracellular solution at room temperature. Extracellular solution contained (in mM): 119 NaCl, 2.5 KCl, 1.5 MgCl₂, 2.5 CaCl₂, 1.25 NaH₂PO₄, 24 NaHCO₃, 10 glucose, 2 Na pyruvate, and 2 Na lactate, bubbled with 95% O₂ and 5% CO₂. Following surgical isolation of the retina, a small piece was embedded in 2% agarose and cut into 200 μm-thick slices on a Vibratome 3000 (Ted Pella, Redding, CA). From the storage chamber, slices were transferred one at a time to the recording chamber, which was perfused continuously (1.5–2 mL/min) with oxygenated extracellular solution supplemented with picrotoxin (100 μM), TPMPA (50 μM), and strychnine (10 μM) to block inhibitory synaptic transmission (except as noted). Control extracellular solution also contained the group III mGluR agonist L-AP4 (10 μM; except in light stimulation experiments), and 0.3 μM TTX was included to block voltage-gated sodium (Na_v) channels. In experiments requiring the reduction of extracellular [Ca²⁺], CaCl₂ was replaced with equimolar MgSO₄. The patch pipette solution contained (in mM): 90 Cs methanesulfonate, 20 TEA-Cl, 10 HEPES, 10 EGTA, 10 sodium phosphocreatine, 2 MgATP, and 0.2 NaGTP, adjusted to pH 7.35 with CsOH. All experiments were performed at room temperature (22°C), except light stimulation experiments, in which extracellular solution was warmed to 26°C by an inline heater. Reagents were obtained from Sigma (St. Louis, MO; all

salts, picrotoxin, strychnine, TPMPA, and DAAO), Tocris Cookson (Ellisville, MO; all modulators of glutamate receptors), and Alomone (TTX).

Cell identification

RGCs were selected on the basis of location in the ganglion cell layer, large somata, and input resistances between 100–600 M Ω . Identification of AII amacrine cells, rod bipolar cells, and ON cone bipolar cells was aided by the addition of Alexa 488 (10 μ M; Molecular Probes, Eugene, OR) to the pipette solution and fluorescent imaging of the cells, which exhibited distinct patterns of dendritic ramification in the inner plexiform layer (Singer and Diamond, 2003; Chavez and Diamond, 2008).

Electrophysiology

All recordings were made with an Axopatch 1D amplifier (Axon Instruments, Sunnyvale, CA) in voltage-clamp mode. Patch electrodes (#0100 glass; World Precision Instruments, Sarasota, FL) had tip resistances of 4–6 M Ω when filled with internal solution. Access resistance (15–30 M Ω) was monitored constantly and not compensated. Data acquisition and analysis were performed with custom macros written in Igor Pro (Wavemetrics, Portland, OR). Data were filtered at 1 kHz and sampled at 2 kHz.

Light stimulation

Slices were prepared under dim red light. Voltage steps were used to illuminate an LED mounted on the top port of a Zeiss inverted microscope. Full-field illumination was focused orthogonally to the main axis of the photoreceptors. Stimulus intensities were typically 10^3 – 10^4 photons/mm²/s, and 3-s stimuli were given at 30 s intervals.

Pressure application of CPPG and kainic acid (KA)

A pneumatic pump (Parker Hannifin, Cleveland, OH) at 4–9 psi was used to apply CPPG (600 μ M) or KA (100 μ M) from a glass pipette positioned in the outer plexiform layer. In some experiments, CPPG and KA were loaded into separate sides of a theta glass pipette; independent application of either compound was confirmed by the failure of CPPG, applied directly to the RGC soma, to produce a response, while direct application of KA to the same cell produced an excitatory response (data not shown). Stimuli (100–300 ms) were delivered at 30 s intervals.

Electrical stimulation

Responses were elicited at 30 s intervals with a stainless steel bipolar electrode (Frederick Haer, Bowdoinham, ME) positioned in the outer plexiform layer.

Immunohistochemistry

Tissue was prepared for light microscopy as described previously (Zhang and Diamond, 2006). Briefly, eyecups from P17 and P22 animals were fixed (D-serine: 4% paraformaldehyde, 0.5% glutaraldehyde, 0.2% sodium metabisulfite; serine racemase (SR): 4% paraformaldehyde) in 0.1 M phosphate buffer (PB) at pH 7.4 for 15–30 min at room temperature. Eyecups were washed several times in 0.1 M phosphate-buffered saline (pH 7.4) with 0.5% sodium borohydride and 0.2% sodium metabisulfite, then cryoprotected at 4°C with graded sucrose solutions (15%, 20% and 30%, 60 min each; then overnight in 30%). The tissue was vertically sectioned (20 μ m thick) on a cryostat, and mounted on glass slides. Slides were rinsed in PBS, blocked in 10% normal donkey serum (NDS, Sigma) in PBS for 1 hour and incubated overnight in primary antibodies of either polyclonal anti-rabbit D-serine (1:200, Gemac, Bordeaux, France), polyclonal anti-goat SR (1:100, Gemac), or a cocktail of monoclonal anti-mouse glutamine synthetase (1:300, Chemicon, Temecula, CA) with D-serine

or SR in 2% NDS plus 1% bovine serum albumin (BSA, Sigma) with 0.3% Triton X-100 at 4°C. Sections were rinsed and incubated for 2 hours at room temperature in Cy3-conjugated donkey anti-rabbit IgG or anti-goat IgG (1:400) or FITC-conjugated anti-mouse IgG (1:400; all from Jackson ImmunoResearch Laboratories, West Grove, PA). Immunofluorescence was visualized with a confocal laser scanning microscope (Zeiss LSM-510; Thornwood, NY) through a 25×, 0.9 NA objective. Image brightness and contrast were adjusted in Adobe Photoshop 6.0.

Antibodies used in this study have been characterized previously in rodent retina by Western blot and immunocytochemistry (Stevens et al., 2003; Dun et al., 2008). The specificity of D-serine and SR antibodies was verified with preadsorption experiments. When polyclonal antibodies to D-serine and SR were preadsorbed with D-serine or polypeptide antigen, respectively (both from Gemac), no fluorescence was detected (Figure 7A3, B2, C3, D2). D-serine immunoreactivity was unaffected by attempted preadsorption with L-serine (Figure 7A4, C4). Additionally, single or double labeling always was accompanied by negative control experiments in which one or two primary antibodies were eliminated and then the one or two appropriate secondary antibodies were applied in single or double labelings. In these cases, only fluorescence specific for the remaining primary antibody was detected (data not shown).

Statistical analysis

Unless otherwise indicated, all data are expressed as mean \pm SD; p values indicate paired or unpaired t-tests, as appropriate (and noted), and $p < 0.05$ was considered significant.

Results

Light responses predict synaptic responses to puff application of CPPG and KA

Acute retinal slices permit physiological stimulation of the circuitry with light (Werblin, 1978), but interpreting pharmacological effects on light responses in the inner retina is complicated by potentially confounding actions in the outer retina. To reduce this problem, we bypassed photoreceptors by stimulating ON and OFF bipolar cells directly in acute slices of rat and mouse retina with focal pressure (“puff”) application of exogenous agents in the outer plexiform layer (OPL; Figure 1K). ON bipolar cells – rod bipolar cells (RBCs) and ON cone bipolar cells (ON CBCs) – were depolarized by puff application of the group II/III mGluR antagonist CPPG (600 μ M, 240 ms) in the continuous presence of the group III mGluR agonist L-AP4 (10 μ M; Nawy, 2004; Chavez et al., 2006). OFF cone bipolar cells (OFF CBCs) were depolarized by puff application of the AMPA/KA receptor (AMPA/KAR) agonist KA (100 μ M, 140 ms). Inhibitory neurotransmission and Na_v channels were blocked in all experiments (see Materials and Methods).

To confirm that synaptic responses in RGCs to CPPG and KA accurately represented the relative contributions of ON and OFF synaptic inputs, sensitivity to light and puff stimulation was compared within individual RGCs. EPSCs, recorded from RGCs under whole-cell voltage clamp ($V_{\text{hold}} = +40$ mV), were evoked by full-field light stimuli (3 s, 10^3 – 10^4 photons/ μm^2 /s). Then, following addition of L-AP4 (10 μ M) to the bath solution, EPSCs were elicited by brief applications of CPPG and KA delivered to the OPL through a double-barreled pipette. RGCs that responded strongly to the onset of a light stimulus, but not to its offset (“ON cells”), responded to puff application of CPPG, but not KA (Figure 1A–C). Conversely, RGCs that responded strongly to light offset, but not onset (“OFF cells”), responded to pressure application of KA but not CPPG (Figure 1D–F). A third group of cells responded strongly to both light onset and offset (“ON-OFF cells”) and also responded well to both CPPG and KA (Figure 1G–I). CPPG and KA responses were reduced almost completely by the L-type voltage-gated calcium (Ca_v) channel blocker isradipine (CPPG: charge transfer (Q_{EPSC}) reduced to 10

$\pm 10\%$ of control; $n = 14$; $p = 0.002$; KA: Q_{EPSC} reduced to $20 \pm 3\%$ of control; $n = 14$; $p = 0.0003$; Figure 1), indicating that puff-evoked currents reflect primarily synaptic release from bipolar cells, rather than direct activation of RGCs. Given the strong agreement between ON/OFF light and CPPG/KA puff responsiveness (Figure 1J), CPPG-evoked and KA-evoked synaptic currents will be referred to here as “ON EPSCs” and “OFF EPSCs,” respectively.

ON and OFF EPSCs in RGCs are primarily NMDAR-mediated

During an evoked response, glutamate released from bipolar cells activates both AMPARs and NMDARs on RGCs (Mittman et al., 1990; Matsui et al., 1998; Chen and Diamond, 2002). More recent work suggests that transmitter release and NMDAR activation may be regulated differently at ON and OFF RGC synapses (Sagdullaev et al., 2006). To compare NMDAR EPSCs activated by ON and OFF inputs to RGCs, we recorded puff-evoked ON and OFF EPSCs in RGCs (Figure 2). CPPG-evoked ON EPSCs ($V_{hold} = +40$ mV) were blocked almost completely by the broad-spectrum NMDAR antagonist R,S-CPP (CPP, $10\ \mu\text{M}$; to $8 \pm 6\%$ of control at $V_{hold} = +40$ mV; $n = 6$; $p = 0.01$; Figure 2A). Accordingly, a plot of Q_{EPSC} versus V_{hold} yielded a J-shaped relation indicating the voltage-dependent block of NMDAR channels by external Mg^{2+} (Mayer et al., 1984; Nowak et al., 1984; Figure 2B). KA-evoked OFF EPSCs also were outwardly-rectifying and blocked by CPP (to $5 \pm 8\%$ of control at $V_{hold} = +40$ mV; $n = 5$; $p = 0.03$; Figure 2C,D). In both cases, the small, CPP-insensitive component exhibited a linear Q_{EPSC} -voltage relationship (Figure 2B,D), consistent with previous work showing that the non-NMDAR component of the EPSC in RGCs is mediated by AMPARs (Lukasiewicz et al., 1997; Chen and Diamond, 2002). Accordingly, the ON EPSC remaining in CPP was blocked by NBQX ($5\ \mu\text{M}$; data not shown). Similar effects of CPP were observed when EPSCs were evoked by brief electrical stimulation ($10\ \mu\text{A} \times 600\ \mu\text{sec}$) with an electrode placed in the OPL (Figure 2E, F), indicating that the large fractional NMDAR component was not an artifact of the puff stimulation. CPPG-evoked ON EPSCs recorded at -70 mV were enhanced by cyclothiazide ($50\ \mu\text{M}$), which blocks AMPAR desensitization, and were not significantly affected by CPP, confirming that the NMDAR antagonist does not block AMPARs on RGCs (Supplementary Figure 1). The predominant contribution of NMDARs to the Q_{EPSC} likely reflects the approximately 50-fold longer open time of NMDAR channels. These kinetic differences between AMPARs and NMDARs were evident in electrically evoked EPSCs (Figure 2E) but were obscured during the prolonged, desynchronized release evoked by puff stimulation.

Different NMDAR subtype combinations mediate ON and OFF EPSCs in RGCs

NR2 subunits determine several important properties of the NMDAR complex, including its affinity for glutamate and glycine. For example, diheteromeric NMDARs containing NR2B subunits exhibit a 10-fold higher affinity for glycine than those containing NR2A (Priestley et al., 1995). NMDARs at ON and OFF RGC synapses are differentially sensitive to glycine (Lukasiewicz and Roeder, 1995), suggesting that they may comprise distinct NMDAR subtypes. To test this idea, we compared the reduction of ON and OFF EPSCs by Ro 25-6981 ($3\ \mu\text{M}$), an NMDAR antagonist exhibiting up to 5000-fold selectivity for receptors containing the NR2B subunit (Fischer et al., 1997). To permit within-cell comparisons, EPSCs were recorded from ON-OFF RGCs that responded strongly to both CPPG and KA. CPPG and KA puffs were delivered to the OPL in alternating sets of 5–10 stimuli in the absence and presence of Ro 25-6981, which reduced ON EPSCs (to $49 \pm 12\%$ of control; $n = 6$; $p = 0.03$; Figure 3A) but exerted no significant effect on OFF EPSCs (to $92 \pm 14\%$ of control; $n = 6$; $p = 0.14$; Figure 3B). Within individual cells, ON responses were significantly more sensitive to Ro25-6981 than were OFF responses ($n = 6$, $p = 0.004$; Figure 3C). Ro 25-6981 sensitivity in ON or OFF RGCs (data not shown) was similar to that observed at the analogous input in ON-OFF cells. Although the mechanism by which Ro 25-6981 acts on NMDARs is not completely understood (Fischer, et al., 1997), our pharmacological results suggest that ON and OFF inputs

to RGCs are mediated by distinct NMDAR subtypes: at ON inputs, a significant fraction of NMDARs appear to contain at least one NR2B subunit, while NR2B NMDARs are largely absent at OFF inputs.

The rod pathway contributes significantly to ON excitation of CBCs and RGCs

At bipolar cell ribbon synapses, the synaptic glutamate concentration during an evoked response varies with release probability (P_r) (Singer et al., 2004). Consequently, modulation of transmitter release would change the glutamate concentration waveform encountered by postsynaptic receptors; because different NMDAR subtypes exhibit distinct affinities for glutamate (Dingledine et al., 1999), this could alter the relative activation of different NMDAR subtypes during the EPSC. To address this possibility at ON synapses, we took advantage of the fact that CPPG puffs, in addition to stimulating ON CBCs directly, also recruit input to ON CBC terminals from the rod pathway (Figure 1K). CPPG-evoked glutamate release from RBCs activates AII amacrine cells (Chavez et al., 2006), which make Connexin36 (Cx36)-containing gap junctions onto ON CBC terminals (Mills et al., 2001; Deans et al., 2002). Blocking excitation of AII amacrine cells with NBQX (Singer and Diamond, 2003; Veruki et al., 2003), then, should decrease transmitter release from ON CBCs onto RGCs. Accordingly, NBQX (5 μ M) reduced ON EPSCs in RGCs to 13 ± 11 % of control ($n = 5$; $p = 0.0006$) (Figure 4A). The NBQX-sensitive EPSC was mediated primarily by NMDARs, as it exhibited an outwardly rectifying Q_{EPSC} -voltage relation (Figure 4B). This effect was not due to direct actions of NBQX on NMDARs, as NBQX did not affect responses in RGCs to exogenous NMDA application (100 μ M; 100 ± 21 % of control; $n = 5$; $p = 0.83$; Figure 4C). Additionally, NBQX did not act directly on mGluR6, as it did not affect CPPG-evoked responses in RBCs (Q_{EPSC} : 92 ± 19 % of control; $n = 7$; $p = 0.19$; Figure 4D), which also express mGluR6 (Nomura et al., 1994). NBQX did, however, reduce CPPG-evoked EPSCs in AII amacrine cells (Q_{EPSC} : 22 ± 17 % of control; $n = 5$; $p = 0.02$; Figure 4E) and ON CBCs (to 24 ± 15 % of control; $n = 6$; $p = 0.009$; Figure 4F). To confirm that the effects in ON CBCs reflected signal transfer via Cx36 gap junctions between AII and ON CBCs, CPPG responses were recorded in wild-type (WT) and Cx36^{-/-} mice (Deans et al., 2002). NBQX reduced CPPG responses in ON CBCs from WT mice (to 44 ± 9 % of control; $n = 5$; $p = 0.04$; Figure 4G,K) but not Cx36^{-/-} mice (79 ± 13 % of control; $n = 4$; $p = 0.18$; WT vs. Cx36^{-/-}: $p = 0.006$; Figure 4H,K). NBQX reduced ON EPSCs in RGCs of WT mice (Q_{EPSC} : 34 ± 8 % of control; $n = 5$; $p = 0.02$; Figure 4I,K) more than in Cx36^{-/-} mice (Q_{EPSC} : 54 ± 12 % of control; $n = 6$; $p = 0.007$; WT vs. Cx36^{-/-}: $p = 0.01$; Figure 4J,K). These results indicate that input from the rod pathway, via AII amacrine cells, contributes significantly to depolarization of ON CBCs and, consequently, ON EPSCs in RGCs.

Activation of ON pathway modulates occupancy of the NMDAR coagonist site

NBQX reduced ON EPSCs substantially even in Cx36^{-/-} RGCs (Figure 4K), suggesting that it may exert other effects within the network to reduce NMDAR activation. One possibility is that NBQX-sensitive receptors drive other cells that release an NMDAR coagonist – either glycine or D-serine – onto RGC NMDARs (Lukasiewicz and Roeder, 1995; Gustafson et al., 2007). For example, both glycinergic amacrine cells and D-serine-containing Müller glial cells express AMPAR/KARs (Peng et al., 1995; Chavez and Diamond, 2008), rendering them sensitive to NBQX. To test this hypothesis, ON EPSCs were recorded from rat RGCs in the absence and presence of saturating concentrations of D-serine (100 μ M), a full agonist at the NMDAR coagonist site that is not normally taken up by glycine transporters (Schell et al., 1995) and does not activate strychnine-sensitive glycine receptors (Schmieden et al., 1993). Under normal conditions D-serine did not enhance ON EPSCs (Q_{EPSC} : 103 ± 22 % of control; $n = 6$; $p = 0.70$; Figure 5A), suggesting that NMDAR coagonist sites are saturated during ON EPSCs. In contrast, ON EPSCs recorded in the presence of NBQX were enhanced by D-serine (Q_{EPSC} : 253 ± 79 % of NBQX alone; $n = 6$; $p = 0.03$; Figure 5B), suggesting that NBQX leads

to a reduction in coagonist site occupancy during EPSCs. Indeed, NBQX reduced the ON EPSC less in the presence of D-serine (Q_{EPSC} : 61 ± 21 % of control; $n = 6$; $p = 0.01$; Figure 5C) than in its absence (Q_{EPSC} : 13 ± 10 % of control; $n = 6$; $p = 0.009$; $p = 0.001$ for absence vs. presence of D-serine). D-serine (100 μ M) did not alter CPPG-evoked EPSCs in AII amacrine cells (Q_{EPSC} : 90 ± 8.5 % of control, $n = 4$, $P = 0.8$; Supplementary Figure 1C), indicating that it exerted no significant actions on the Ca-permeable AMPARs that mediate synaptic inputs to AII (Singer and Diamond, 2003). These results suggest that CPPG stimulation of the ON pathway typically evokes coagonist release sufficient to saturate NMDARs, but that blocking AMPARs decreases coagonist release and relieves saturation of the NMDAR coagonist site.

Taken together, these results suggest that blocking AMPARs reduces NMDAR activation on RGCs via two mechanisms: 1) by blocking activation of AII, thereby reducing ON CBC depolarization and consequent glutamate release (Figure 4E-K); 2) by reducing release of an NMDAR coagonist, either glycine or D-serine (Figure 5A,B). Accordingly, NBQX applied in the presence of D-serine reduced the ON EPSC in WT mice but exerted no significant effect on ON EPSCs in Cx36 $-/-$ mice (Figure 5D,E).

Although evoked release appears to saturate the NMDAR coagonist sites (Figure 5A), it is unclear whether the sites are also saturated by ambient levels of coagonist (Vyklícky et al., 1990; Wilcox et al., 1996). To address this issue at ON synapses, we measured the effects of exogenous, saturating concentrations of NMDA and D-serine on holding currents and ON EPSCs in RGCs. Bath application of NMDA (100 μ M) increased the holding current (to 229 ± 41 % of control; $n = 5$; $p = 0.002$; Figure 5F) and decreased the evoked ON EPSC (to 39 ± 24 % of control; $n = 5$; $p = 0.02$). Similar effects were observed with 300 μ M NMDA (data not shown), indicating that 100 μ M NMDA was sufficient to saturate NMDARs. Subsequent addition of saturating D-serine (100 μ M) further increased the holding current (to 303 ± 74 % of control; $n = 5$; $p = 0.02$; Figure 5F) and decreased the ON EPSC (to 9 ± 7 % of control; $n = 5$; $p = 0.01$). The existence of an ON EPSC in the presence of NMDA that is occluded by D-serine confirms that CPPG evokes release of NMDAR coagonist and indicates that NMDARs at ON synapses are not saturated by ambient levels of coagonist.

Coagonist-site occupancy controls NMDAR subtype contribution to ON EPSCs

The above results demonstrate that NMDAR activation during the ON EPSC is regulated by occupancy of the coagonist site. Because NMDARs containing NR2A versus NR2B subunits have different affinities for glycine (Priestley et al., 1995), changes in coagonist release could modulate the relative contributions of these receptor subtypes. To test this hypothesis, we determined whether changing the amount of available coagonist alters the fractional contribution of NR2B-containing NMDARs to the ON EPSC. In control conditions (i.e., in the absence of NBQX or D-serine), the NR2B antagonist Ro25-6981 reduced the NMDAR component of ON EPSCs (to 59 ± 10 %; $n = 6$; $p = 0.003$; Figure 6A, F), consistent with our previous results in ON-OFF cells (Figure 3). The continuous presence of saturating D-serine did not change the fractional contribution of NR2B-containing receptors (Q_{EPSC} remaining in Ro25-6981 = 57 ± 18 % of Q_{EPSC} in D-serine; $n=6$; $p=0.005$; $p=0.84$ vs. control; Figure 6B, F), consistent with our earlier finding that evoked coagonist release saturates all NMDARs (Figure 5A). In the presence of NBQX, which reduces coagonist release (Figure 5), the block by Ro25-6981 was significantly enhanced (Q_{EPSC} remaining in Ro25-6981 = 26 ± 11 % of Q_{EPSC} in NBQX; $n = 6$; $p = 0.02$; $p = 0.0003$ vs. control; Figure 6C, F). This was due to a reduction in coagonist site occupancy, because in the continuous presence of both D-serine and NBQX, the block by Ro25-6981 was similar to that in control conditions (to 57 ± 27 % of Q_{EPSC} in D-serine + NBQX; $n = 7$; $p = 0.03$; $p = 0.93$ vs. control; Figure 6D, F). These results indicate that reducing coagonist release from an AMPAR-driven cell (or cells) limits the activation of non-NR2B NMDARs in favor of higher-affinity, NR2B-containing subtypes.

NMDARs are not necessarily saturated by synaptically released glutamate (Mainen et al., 1999; McAllister and Stevens, 2000; Ishikawa et al., 2002; Pankratov and Krishtal, 2003). It is possible, therefore, that modulating glutamate release from ON CBCs could alter the relative activation of different NMDARs independently of coagonist binding. As mentioned above, because a single ribbon can release multiple vesicles within a millisecond, the peak glutamate concentration sensed by receptors opposing the ribbon synapses of bipolar cells varies with P_R (Singer et al., 2004). If the activation of relatively low-affinity (i.e., non-NR2B) NMDARs at ON inputs to RGCs is particularly limited by the synaptic glutamate concentration, then decreasing P_R may increase the fractional block of the EPSC by an NR2B-specific antagonist. To test this hypothesis, ON EPSCs were evoked in the presence of saturating D-serine – to negate possible effects of changing P_R on coagonist release – and NBQX. Under these conditions, reducing external Ca^{2+} from 2.5 mM to 1.0 mM significantly decreased the ON EPSC (to $61 \pm 19\%$; $n=7$; $p=0.02$), but the degree of block by Ro25-6981 was unchanged (2.5 mM Ca: Ro reduced Q_{EPSC} to $60 \pm 22\%$ of control, $n = 7$; $p = 0.02$; 1.0 mM Ca: Ro reduced Q_{EPSC} to $63 \pm 23\%$, $n = 7$, $p = 0.02$; Ro block in 2.5 vs. 1.0 mM Ca: $p = 0.57$ [paired]; Figure 6E). This result suggests that modulation of coagonist release, but not glutamate release, affects relative NMDAR subunit contributions to CPPG-evoked EPSCs.

Endogenous D-serine contributes to ambient occupancy of the coagonist site

The data presented thus far indicate that evoked coagonist release contributes to NMDAR activation during ON EPSCs. Is the coagonist glycine, D-serine, or some combination of the two? Glycine is an obvious candidate, because half the amacrine cells in the inner retina use glycine as their primary neurotransmitter (MacNeil and Masland, 1998; Menger et al., 1998). On the other hand, recent reports suggest that D-serine acts as an endogenous coagonist for NMDARs in several regions of the CNS, including the retina (Martina et al., 2003; Panatier et al., 2006; Gustafson et al., 2007), where Müller glial cells express D-serine and its synthetic enzyme, serine racemase (Stevens et al., 2003). (D-serine expression in RGCs, evident in newborn mice, is significantly diminished by the third postnatal week; Dun et al., 2008.) We also detected immunoreactivity for both D-serine and serine racemase in P17 and P21 rat retina (Figure 7A-D). Co-localization of D-serine with glutamine synthetase, a Müller cell marker (Riepe and Norenburg, 1977), was particularly strong at P22 (Figure 7C2), but neuronal expression of D-serine and serine racemase was evident at both ages.

To evaluate whether D-serine contributes to NMDAR activation at ON inputs, we tested the effects of D-amino acid oxidase (DAAO; 100 $\mu\text{g}/\text{mL}$), an enzyme that degrades D-serine but not glycine (Dixon and Kleppe, 1965; Molla et al., 2006), on CPPG-evoked ON EPSCs. Perfusion with DAAO for a minimum of 20 minutes decreased ON EPSCs (to $72 \pm 10\%$ of control; $n = 6$; $p = 0.02$; Figure 7E). This reduction could reflect a decrease in the amount of ambient coagonist and/or a decrease in evoked coagonist release during the EPSC. To distinguish these two possibilities, we tested the effects of DAAO on ON EPSCs in the continuous presence of NMDA (Figure 7F). DAAO reduced the steady state holding current at +40 mV (from 335 ± 153 pA to 201 ± 98 pA; $n = 6$; $p = 0.01$) but had no effect on the amplitude of the evoked ON EPSC ($110 \pm 90\%$ of NMDA alone; $n = 6$; $p = 0.69$). Although effects of DAAO on the evoked response could be diminished due to saturation of the coagonist site by evoked release of glycine or incomplete elimination of D-serine, these results suggest that D-serine contributes more to ambient coagonist site occupancy rather than activation during an evoked response.

To test this idea further, we examined the effects of DAAO on the NMDAR subunit contribution to the ON EPSC. Experiments shown in Figure 6 indicated that NBQX changes the relative contribution of NR2B NMDARs to the ON EPSC by modulating coagonist occupancy: NR2B NMDARs mediated a larger fraction of the EPSC when coagonist release

was reduced, an effect that was reversed with the addition of saturating coagonist (Figure 6C, D, F). These results suggest that NR2B NMDARs have a different (higher) affinity for released coagonist than other NMDARs. In functional studies comparing coagonist affinity in recombinant diheteromeric NR1/NR2A and NR1/NR2B NMDARs, NR2B NMDARs exhibited a ten-fold higher affinity for glycine than did NR2A NMDARs, while affinity for D-serine was similar between the two subtypes (Priestley et al., 1995). Consistently, in the presence of DAAO, the NR2B antagonist Ro 25-6981 blocked the ON EPSC to a similar extent (Q_{EPSC} reduced to $49 \pm 17\%$ of control; $n = 6$; $p = 0.03$) as in the absence of DAAO (Q_{EPSC} reduced to $59 \pm 10\%$; $n = 6$; $p = 0.003$; Ro effect with vs. without DAAO: $p = 0.23$; Figure 7G). Thus, a reduction in D-serine release alone cannot explain the effects of NBQX on coagonist site occupancy. These results suggest that D-serine and glycine play complementary roles in contributing to NMDAR activation in RGCs.

Discussion

The results presented here provide several new pieces of information about synaptic activation of NMDARs on RGCs in the retina. ON inputs to RGCs utilize NMDARs exhibiting NR2B-like pharmacology to a much greater extent than do OFF inputs (Figure 3). Moreover, synaptic activation of the retinal circuitry evokes the release of NMDAR coagonist (Figure 5), which contributes to receptor activation during ON EPSCs and, in fact, modulates the relative contribution of different NMDAR subtypes (Figure 6). Our results suggest that both D-serine and glycine act as endogenous NMDAR coagonists on RGCs (Figure 7), a hybrid arrangement reflecting the prominence of both transmitters in the retinal circuitry (Figure 8).

In this study, ON and OFF pathways were selectively activated by puff application of CPPG and KA to the OPL. Sensitivity to this exogenous stimulation was tightly correlated to light responsivity (Figure 1). Notably, within-cell comparisons of responses to puff and light stimulation indicated that, at least in juvenile (P17-23) rats, a functional continuum exists between “ON,” “ON-OFF,” and “OFF” RGCs (Figure 1J). This may reflect ongoing activity-dependent developmental pruning of RGC dendrites that gradually reduces the fraction of ON-OFF RGCs through the end of the fourth postnatal week (Tian and Copenhagen, 2003).

ON and OFF inputs to RGCs activate distinct NMDAR subtypes

NMDARs mediate synaptic input to RGCs in every species studied to date (Mittman et al., 1990; Matsui et al., 1998; Chen and Diamond, 2002; Sagdullaev et al., 2006), but specific functions for NMDARs, or roles for different NMDAR subtypes in RGC signaling, have not been identified. Here we show in rat RGCs that ON and OFF inputs utilize distinct NMDAR subunit combinations (Figure 8), analogous to recent results in other CNS neurons that receive inputs from multiple, functionally distinct pathways. For example, CA1 pyramidal neurons in the hippocampus receive perforant path input via synapses that contain a larger fraction of NR2B NMDARs than those mediating Schaffer collateral input (Kawakami et al., 2003; Arrigoni and Greene, 2004). In neocortical pyramidal cells, the comparatively slow kinetics of NR2B NMDARs underlies input-specific differences in EPSP integration (Kumar and Huguenard, 2003). In the retina, specific physiological roles for particular NMDAR subtypes in the ON and OFF pathways remain to be determined, but our results contribute to an emerging pattern of asymmetries in the ON and OFF inputs to RGCs (Chichilnisky and Kalmar, 2002; Sagdullaev et al., 2006). One possibility is that the differential expression of low- and high-affinity subtypes may offset pathway-specific differences in synaptic availability of coagonist to maintain similar levels of NMDAR activation at ON and OFF inputs. Activation of non-NR2B NMDARs, which have relatively low affinity for glycine (Priestley et al., 1995), may require higher glycine levels that may exist in the OFF sublamina, where AII amacrine cells release glycine directly onto OFF bipolar cell terminals (Kolb, 1979), while higher-affinity

NR2B NMDARs predominate in the ON layers of the IPL, where glycinergic inputs are more scarce (Pow and Hendrickson, 2000).

Another possibility is that distinct expression of different NR2 subunits reflects either a cause or a consequence of the developmental segregation of the ON and OFF sublamina (Tian and Copenhagen, 2003). In other parts of the CNS, the appearance of particular NR2 subunits correlates with distinct developmental stages. For example, synapses in the neonatal hippocampus express primarily NR2B-containing receptors, until NR2A-containing receptors appear during the second postnatal week (Monyer et al., 1994; Kutsuwada et al., 1996), when they are incorporated into the postsynaptic density, possibly as a necessary step in activity-dependent synaptic maturation (Bellone and Nicoll, 2007). Additionally, distinct NMDAR subtype expression may trigger differences in dendritic branching density, analogous to a recent report in developing *Xenopus* tectal neurons (Ewald et al., 2008). Expansive developmental studies of NR2 subunit expression, physiological activation and dendritic modeling in RGCs are required to address whether the onset or cessation of expression of particular NMDAR subtypes in RGCs contributes to dendritic segregation between, and branching within, functional layers of the IPL. Finally, it should be noted that, because the mechanism by which NR2B-selective antagonists Ro 25-6981 and ifenprodil act on NMDARs is incompletely understood (Fischer, et al., 1997), immunoelectron microscopy will be required to confirm the existence of NR2B-containing receptors at ON synapses (Zhang and Diamond, in preparation).

Coagonist release from within the retinal circuitry modulates NMDAR activation

When it was first discovered that NMDAR activation required a coagonist in addition to glutamate, the coagonist was presumed to be glycine (Johnson and Ascher, 1987). Given the paucity of glycinergic transmission in most forebrain regions, it was generally assumed that the coagonist site was bound by ambient glycine, which is present in cerebrospinal fluid at concentrations several times higher than its EC_{50} at the coagonist site (Ferraro and Hare, 1985; Johnson and Ascher, 1987). Accordingly, the coagonist site generally was thought to be saturated (Llano et al., 1988; Bashir et al., 1990; Mothet et al., 2000), despite several counterexamples (e.g., Forsythe et al., 1988; Thomson et al., 1989; D'Angelo et al., 1990; Lester et al., 1993). Previous work in salamander retina suggested that glycine released from amacrine cells can reach NMDARs on RGCs (Lukasiewicz and Roeder, 1995), but the issue of ambient saturation was not addressed. Here, we isolated synaptic activation of the NMDAR coagonist site by eliciting EPSCs in the presence of saturating concentrations of NMDA (Figure 5I). The EPSCs evoked under these conditions, therefore, reflect synaptic release of coagonist and successful activation of the coagonist site. This is consistent with previous work showing that coagonist released from within the retinal network contributes to NMDAR activation on RGCs (Lukasiewicz and Roeder, 1995; Stevens et al., 2003; Gustafson et al., 2007), and it represents the first direct demonstration that synaptic stimulation elicits coagonist release to activate NMDARs.

In this decade, D-serine has emerged as a likely endogenous NMDAR coagonist in several brain regions (Mothet et al., 2000; Panatier et al., 2006), including the retina (Stevens et al., 2003; Gustafson et al., 2007). D-serine and its synthetic enzyme, serine racemase, are found in glial cells in the hippocampus, supraoptic nucleus and retina (Mothet et al., 2000; Stevens et al., 2003; Panatier et al., 2006). Although D-serine and serine racemase expression in the rodent retina decreases during development (Dun et al., 2008), functional expression is still evident in adult rat retina (Stevens et al., 2003), and it was clearly present at the ages studied here (Figure 7). In the supraoptic nucleus, physiological modulation of the physical juxtaposition of synapses and surrounding glial processes, which release D-serine, regulates NMDAR activation and synaptic plasticity (Panatier et al., 2006). Interestingly, in that case,

modulating the effective synaptic concentration of D-serine affected NMDAR EPSC amplitude without changing the relative contribution of NR2B and non-NR2B NMDARs, both of which were activated by synaptic stimulation (Pantatier et al., 2006). This is consistent with pharmacological studies of recombinant NMDARs in a heterologous expression system indicating that NR2B and NR2A NMDARs exhibit similar affinity for D-serine (Priestley et al., 1995). In contrast, NR2B NMDARs exhibit a ten-fold higher affinity for glycine compared to NR2A NMDARs (Priestley et al., 1995). Our observation that reducing coagonist release favors activation of NR2B NMDARs (Figure 6) argues, then, that synaptically released glycine activates NMDARs in the ON pathway. Our results also indicate, however, that D-serine contributes to NMDAR activation, as reported in salamander retina (Stevens et al., 2003; Gustafson et al., 2007). Our observation that D-serine degradation decreases ambient NMDAR activation without affecting evoked responses (Figure 7) is consistent with a scenario in which D-serine released from Müller glia, perhaps in a diffuse fashion characteristic of many modulatory neurotransmitters, contributes to ambient, submaximal occupancy of the coagonist site, while the transient, synaptic release of glycine from amacrine cells contributes to NMDAR activation during EPSCs (Figure 8). These contrasting roles may reflect, in part, the avid uptake of glycine in the retinal circuitry (Pow and Hendrickson, 2000), which may cause glycine to be more tightly regulated than D-serine and limit its action to evoked synaptic events. An interesting, unresolved question concerns whether amacrine cells release glycine at excitatory synapses, or if NMDARs are activated by glycine spillover from nearby inhibitory synapses, as in the spinal cord (Ahmadi et al., 2003).

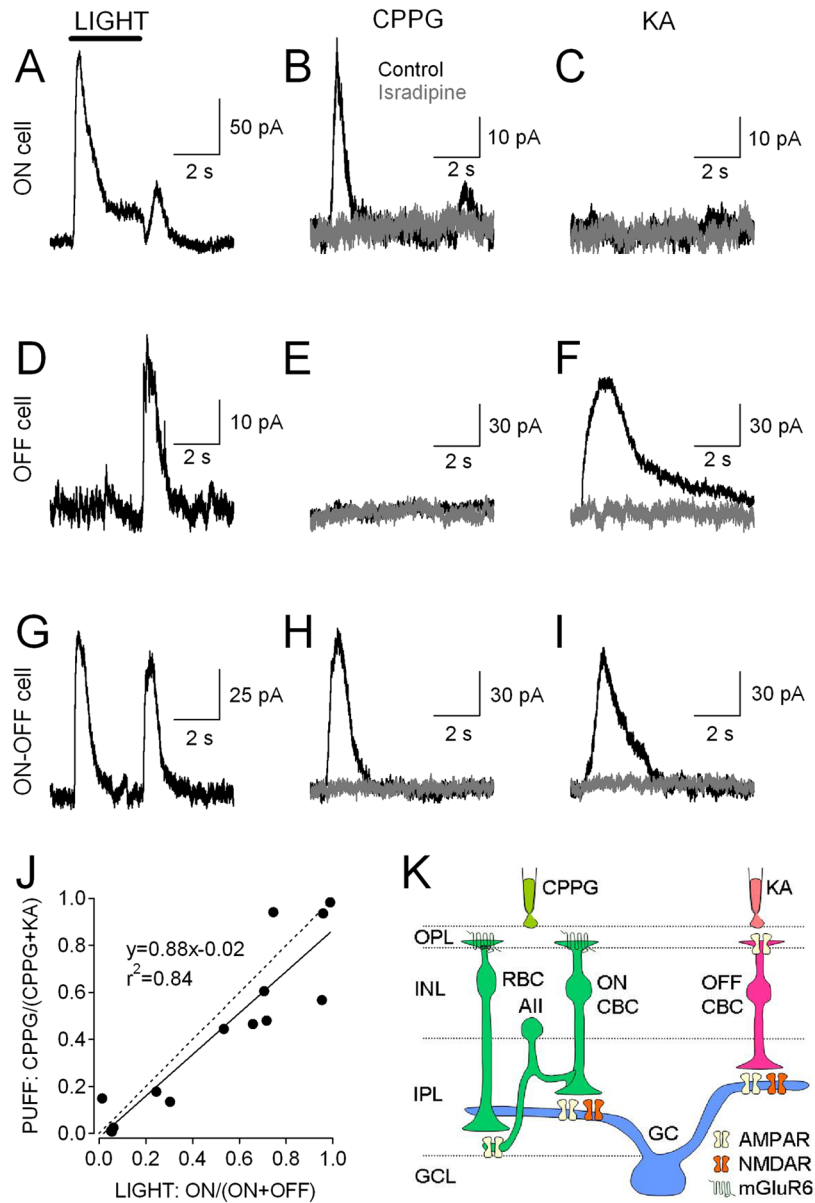

Figure 1.

EPSCs elicited by light and pharmacological stimulation of ON and OFF bipolar cells. *A–I*, responses from three different RGCs elicited by three kinds of stimulation: a 3-s, full-field light stimulus at an intensity of 10^3 – 10^4 photons/ $\mu\text{m}^2/\text{s}$ (*A, D, G*); pressure application of CPPG (600 μM , 240 ms) in the OPL (*B, E, H*); and pressure application of KA (100 μM , 140 ms) in the OPL (*C, F, I*). Responses were recorded from ON (*A–C*), OFF (*D–F*), and ON-OFF (*G–I*) RGCs. Puff-evoked responses were blocked by the L-type Ca_v channel antagonist isradipine (10 μM , gray traces), indicating that they required synaptic transmission. $V_{\text{hold}} = +40$ mV for all EPSCs. *J*, correlation between light responses (X axis) and puff responses (Y axis). EPSCs charge transfer (Q_{EPSC}) was calculated for 3-s windows following light onset and light offset and from the time of CPPG or KA puff stimulation until the EPSC amplitude returned to 5% of its peak value. *x* values represent ON light-evoked Q_{EPSC} as a fraction of total (ON + OFF) light-evoked Q_{EPSC} , while *y* values represent CPPG Q_{EPSC} as a fraction of total (CPPG + KA) Q_{EPSC} . Filled symbols denote individual cells ($n=14$), solid line shows linear regression and

dashed line represents unity. *K*, Schematic of retinal circuit showing parallel ON and OFF pathways activated by CPPG and KA, respectively.

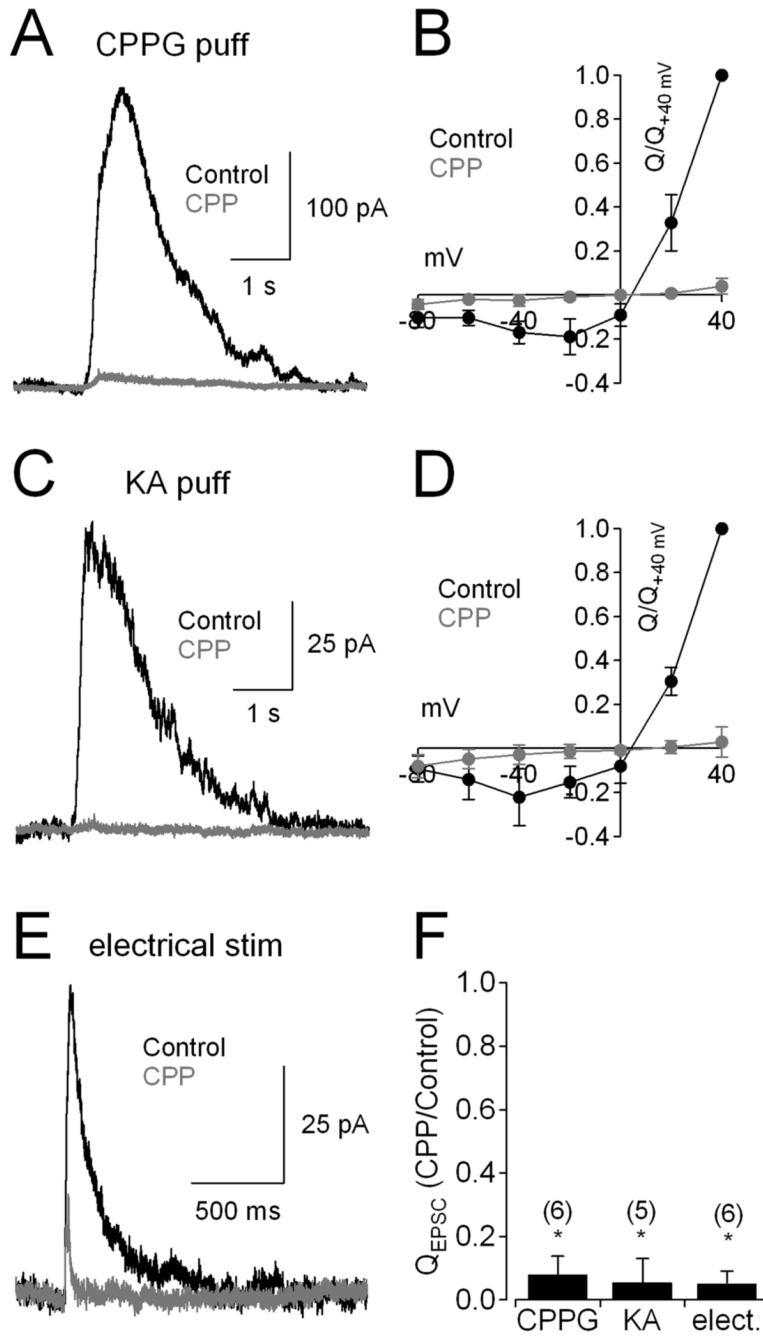

Figure 2. RGC EPSCs are mediated primarily by NMDARs. *A*, CPPG-evoked (“ON”) EPSCs recorded from RGCs ($V_{\text{hold}} = +40 \text{ mV}$) are blocked almost completely by the NMDAR antagonist R,S-CPP ($10 \mu\text{M}$, gray trace). *B*, ON EPSCs exhibited the *J*-shaped charge-voltage relationship that is characteristic of NMDARs; the small, CPP-insensitive component exhibited an ohmic (linear) conductance (gray symbols). For each cell, data points were normalized to the control Q_{EPSC} recorded at $+40 \text{ mV}$. *C–D*, As in *A* and *B*, but EPSCs were elicited by KA. *E*, electrically-evoked EPSCs were recorded from the same cells as shown in *C*. *F*, Fraction of Q_{EPSC} remaining in the presence of CPP compared across stimulation modalities (KA puff, CPPG puff, electrical stimulation). *n* values are indicated in parentheses.

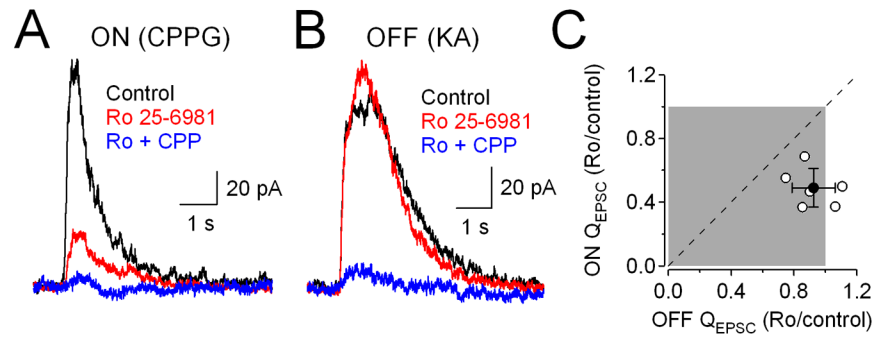

Figure 3.

CPPG-evoked ON EPSCs and KA-evoked OFF EPSCs recorded from ON-OFF RGCs. *A* and *B*, CPPG-evoked (*A*) and KA-evoked (*B*) EPSCs ($V_{\text{hold}} = +40$ mV) recorded from the same cell in the absence and presence of the NR2B NMDAR antagonist Ro 25-6981 (3 μM). *C*, correlation between the fraction of ON and OFF Q_{EPSC} remaining in the presence of Ro 25-6981. *Closed marker* represents average \pm SD ($n=6$); *open markers* represent data from individual cells. *Dashed line* indicates equal inhibition of ON and OFF EPSCs. Ro25-6981 reduced the ON component of the EPSCs more than the OFF component ($p=0.004$, paired t test).

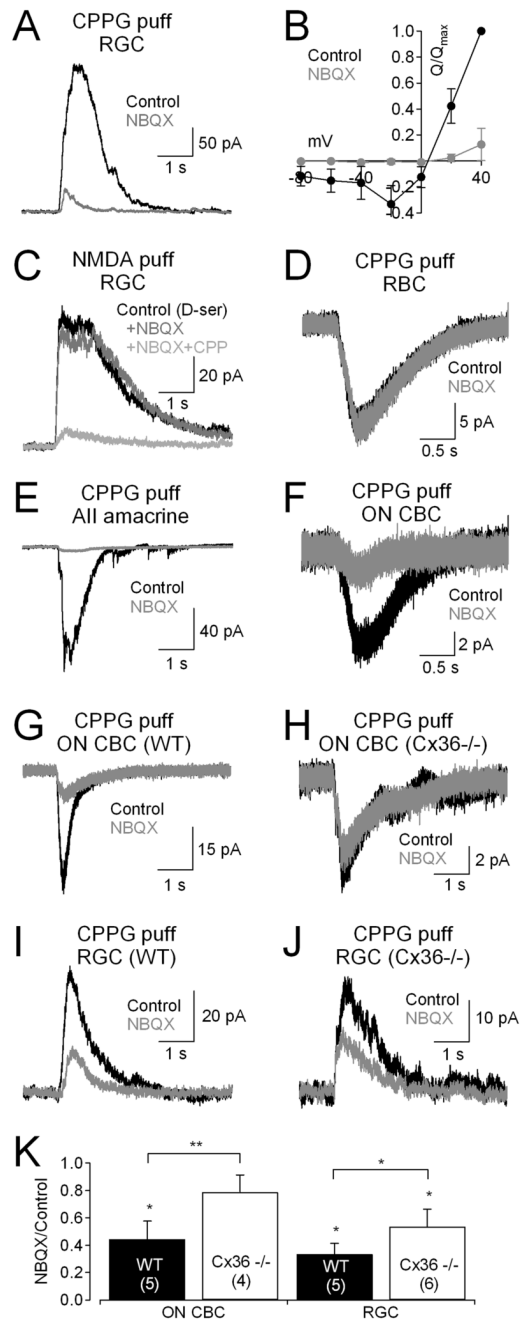

Figure 4.

NBQX reduces NMDAR EPSCs by blocking input from the rod pathway. *A*, CPPG-evoked EPSCs were reduced by NBQX (5 μ M). *B*, the NBQX-sensitive component of the EPSC exhibited a J-shaped voltage dependence, indicating that it was mediated primarily by NMDARs. *C*, NBQX does not block NMDARs, as it did not affect responses in RGCs to exogenous NMDA (100 μ M; $V_{\text{hold}} = +40$ mV). *D*, NBQX did not effect CPPG responses in RBCs, indicating that it did not act on mGluR6. *E*, NBQX blocked CPPG-evoked EPSCs in All amacrine cells. *F*, NBQX strongly reduced CPPG responses in ON CBCs. *G*, As in *F*, but in a wild-type (WT) mouse ON CBC. *H*, NBQX did not affect CPPG responses in ON CBCs from Cx36^{-/-} mice. *I*, NBQX reduced CPPG-evoked EPSCs in RGCs from WT mice. *J*,

NBQX also reduced CPPG-evoked EPSCs in Cx36 $-/-$ mice, but to a lesser extent than in WT. *K*, Summarized effects of NBQX on CPPG-evoked responses in ON CBCs and RGCs. *n* values are indicated in parentheses.

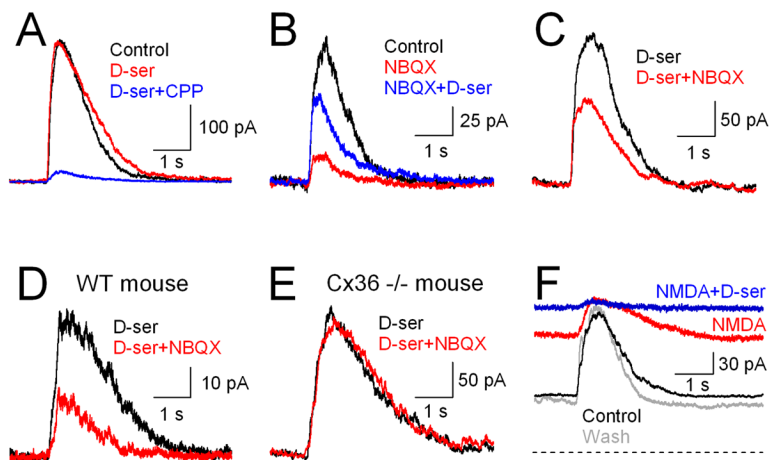

Figure 5.

Synaptic release of coagonist contributes to NMDAR activation. *A*, D-serine (100 μ M) did not affect CPPG-evoked EPSCs, indicating that the NMDAR coagonist site is saturated during evoked responses. *B*, D-serine potentiates the EPSC in the presence of NBQX, indicating that NBQX relieves saturation of the coagonist site. *C*, NBQX's reduction of CPPG-evoked EPSCs was less in the presence of D-serine. *D*, NBQX reduced EPSCs in WT mice in the presence of D-serine. *E*, NBQX exerted no effect on EPSCs in the presence of D-serine in Cx36 $-/-$ mice. *F*, Addition of NMDA (100 μ M, red trace) to the superfusion solution increased the holding current and reduced CPPG-evoked EPSC amplitude ($V_{\text{hold}} = +40$ mV). Subsequent addition of D-serine (100 μ M, blue trace) further increased the holding current and eliminated the EPSC. NMDA and D-serine washed out (gray trace). *Dashed line* indicates zero holding current.

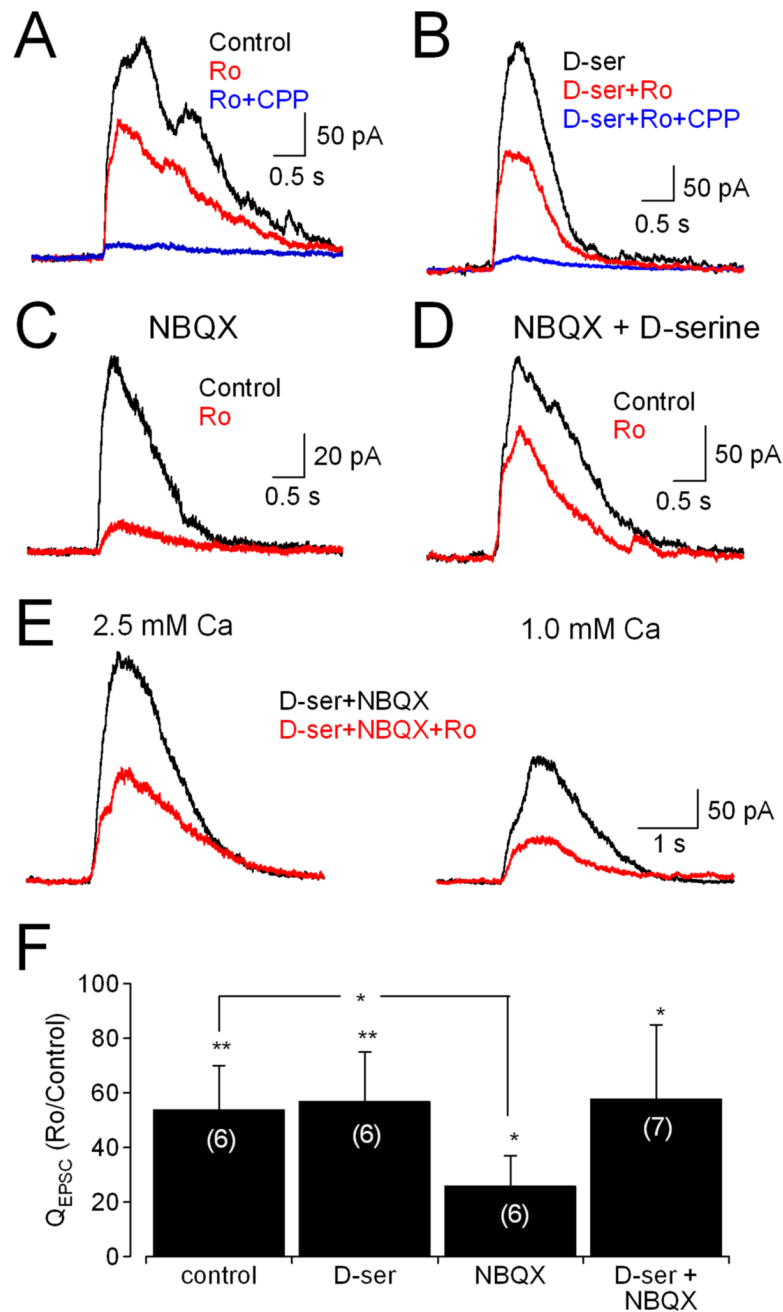

Figure 6.

Synaptic release of coagonist modulates relative contribution of different NMDAR subtypes to the EPSC. $V_{\text{hold}} = +40$ mV in all experiments. *A*, CPPG-evoked EPSCs were reduced by the NR2B NMDAR antagonist Ro 25-6981 (3 μ M). *B*, Ro 25-6981 exerted similar effects in the presence of D-serine (100 μ M). *C*, In the presence of NBQX, Ro 25-6981 blocked a larger fraction of the CPPG-evoked EPSC. *D*, The increased effect of Ro 25-6981 was eliminated in the presence of the NMDAR coagonist D-serine. *E*, Ro25-6981 reduced CPPG-evoked EPSCs to similar extents in 2.5 mM and 1.0 mM Ca²⁺_o. Recordings are from the same cell in the continuous presence of 5 μ M NBQX and 100 μ M D-serine. *F*, Effects of Ro 25-6981 on EPSCs under different pharmacological conditions. *n* values are indicated in parentheses.

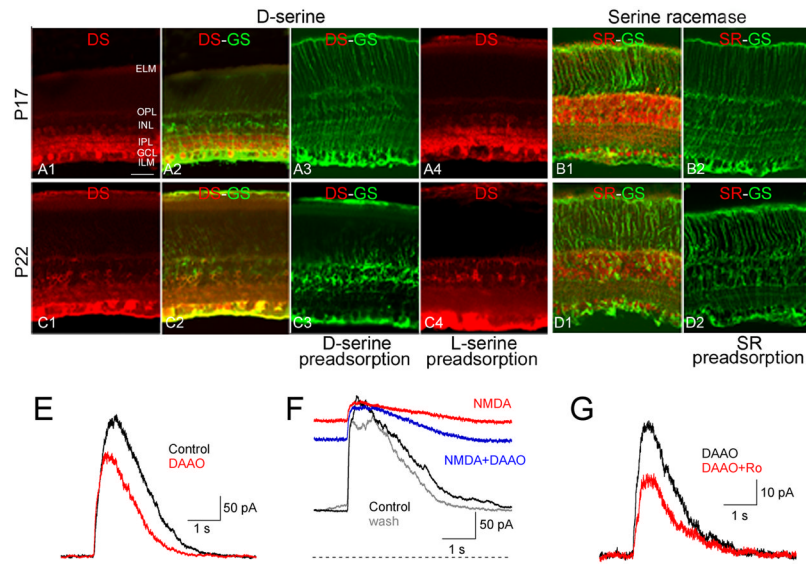

Figure 7.

D-serine and glycine play complementary roles in activating NMDARs. *A*, Immunoreactivity (IR) for D-serine (DS) in P17 rat retina. DS IR was evident in the inner plexiform layer (IPL), the ganglion cell layer (GCL), the inner nuclear layer (INL) and the outer plexiform layer (OPL; *A1*) and was colocalized with glutamine synthetase (GS), a Müller cell marker (*A2*). ELM: external limiting membrane; ILM: internal limiting membrane. DS IR was eliminated by preadsorption of DS (*A3*) but not L-serine (*A4*). *B*, Serine racemase (SR) IR in P17 rat retina. SR IR was evident primarily in the INL and GCL (*B1*), but no SR IR was detected following preadsorption with SR antigen peptide (*B2*). *C*, As in *A* but in P22 retina. DS IR was weaker in the IPL and stronger in the ELM and ILM compared with P17. *D*, As in *B* but in P22 retina. Scale bar in *A1* (50 μ m) applies to all panels in *A-D*. *E*, Degradation of D-serine with DAAO (100 μ g/mL) reduced CPPG-evoked EPSCs. *F*, Exogenous NMDA increased holding current and decreased CPPG-evoked EPSCs (red trace, $V_{\text{hold}} = +40$ mV). In the presence of NMDA, DAAO reduced the holding current but not the EPSC (blue trace). Both NMDA and DAAO washed out (gray trace). *Dashed line* indicates zero holding current. *G*, Ro 25-6981 reduced CPPG-evoked EPSCs in the presence of DAAO.

Figure 8. Multiple NMDARs and coagonists in the inner retina. Simplified schematic illustrating distinct NMDAR subtypes at ON and OFF synapses onto RGCs (GC). ON synapses contain NR2B and non-NR2B NMDARs, and OFF synapses express primarily non-NR2B NMDARs (see Figure 3). D-serine (gray), perhaps released diffusely from Müller glial cells, may contribute primarily to ambient coagonist site occupancy. Glycine (violet), likely released from amacrine cells, may increase coagonist site occupancy during evoked responses.
